⚡ FlexQL

A High-Performance SQL-like Database Engine

Design Document

Repository	https://github.com/Ludirm02/FlexQL
Language	C++17 (zero external database libraries)
Architecture	Multithreaded TCP Client-Server with Buffer Pool
Peak Throughput	~985,000 rows/sec (10M row benchmark)
Persistence	Page-based disk storage + WAL crash recovery

1. Project Overview

FlexQL is a fully custom SQL-like relational database engine built entirely from scratch in C++17 — no third-party database libraries, no SQLite bindings, no embedded engines. It was designed as a university assignment to deeply understand how real-world database systems work internally: how they store data on disk, parse and execute queries, manage memory under load, handle concurrent access safely, and survive crashes without losing committed data.

The system is architected as a TCP client-server application. The server runs as a background daemon that accepts connections from any number of clients simultaneously. Each client communicates using a clean C API (flexql.h) that closely mirrors SQLite's interface, making it straightforward to write programs that talk to FlexQL. There is also an interactive REPL terminal where you can type SQL commands directly.

The engineering goal was not just correctness — it was performance. The server is benchmarked against 10 million rows, and every design decision from how bytes are laid out on disk to how the hash map handles collisions was made with that scale in mind. The result is a system that sustains approximately 985,000 inserts per second and responds to point queries in under 0.025 milliseconds on average.

1.1 Repository & Quick Links

Source Code	https://github.com/Ludirm02/FlexQL
Language	C++17 (compiled with -O3 -march=native -flto)
Build System	GNU Make + CMake (both supported)
Server Binary	bin/flexql_server
Client Binary	bin/flexql-client
Benchmark	bin/flexql_benchmark
Default Port	9000 (configurable via argv)

1.2 What FlexQL Supports

SQL commands supported:

- CREATE TABLE with INT, DECIMAL, VARCHAR(n), TEXT, DATETIME column types and PRIMARY KEY constraints
- INSERT INTO ... VALUES (...) with multi-row batch syntax and optional TTL / EXPIRES clauses
- SELECT * FROM table and SELECT col1, col2 FROM table with optional WHERE and ORDER BY
- WHERE clause with a single condition using =, !=, <, <=, >, >= operators

- INNER JOIN between two tables with an ON condition and optional WHERE filter
- DELETE FROM table (full table clear, resets data and index)

Client API:

- flexql_open(host, port, &db) — connect to server
- flexql_exec(db, sql, callback, arg, &errmsg) — execute any SQL statement
- flexql_close(db) — disconnect and free resources
- flexql_free(ptr) — free memory allocated by the API

2. System Architecture

The diagram below shows every major component and how they connect. Read it top to bottom: the user's code (or the REPL) sits at the top, then the client library, then the TCP boundary, then the server-side thread pool, then the SQL engine with its cache and index, and finally the buffer pool that manages disk I/O.

2.1 Client Side

The client side has two entry points: the REPL and the C API. Both ultimately call the same underlying functions in flexql_client.cpp.

REPL (repl_main.cpp)

The REPL is a simple interactive terminal. It reads lines from stdin, accumulates them until a semicolon is found (supporting multi-line SQL), then calls flexql_exec. Results are printed in the format 'COLUMN_NAME = value'. Typing .exit or .quit disconnects cleanly.

C API (flexql_client.cpp)

This is what user programs link against. It implements the four required functions. Internally it opens a TCP socket, sends queries using the wire protocol, reads the response, and invokes the callback function once per result row. The FlexQL struct is kept opaque — callers only ever hold a pointer to it and never inspect its internals.

```
struct FlexQL {         // Internal — hidden from callers
    int fd;             // TCP socket file descriptor
};

// Public API — all callers see is the typedef:
typedef struct FlexQL FlexQL;
```

2.2 Wire Protocol

The client and server communicate over a custom binary/text hybrid protocol. There are two modes: a text mode (used by the REPL for human-readable debugging) and a binary mode (used when flexql_exec sends a QB header). Binary mode avoids all tab-escape overhead and is significantly faster for large result sets.

```
Client → Server  (Text mode):        Client → Server  (Binary mode):
──────────────────────────────       ────────────────────────────────
Q <len>\n                            QB <len>\n
<sql bytes>                          <sql bytes>

Server → Client  (Text response):    Server → Client  (Binary response):
──────────────────────────────────   ──────────────────────────────────────
OK <ncols>\n                         0x01 [OK frame]
COL\tcol1\tcol2\t...\n              uint32: ncols
ROW\tval1\tval2\t...\n              uint32: nrows
ROW\tval1\tval2\t...\n              [uint16: col_name_len][col_name]...
END\n                               [uint32: val_len][val_bytes]...
```

```
Error (text):                          Error (binary):
ERR\t<escaped message>\n              0x02 [ERROR frame]
                                       uint32: msg_len
                                       [message bytes]
```

TCP_NODELAY is set on every socket to eliminate Nagle's algorithm delays. Socket send and receive buffers are tuned to 16MB each to handle large result sets without stalling.

2.3 Server Side

The server (server_main.cpp) does the following on startup:

1. Creates a TCP server socket, sets SO_REUSEADDR and SO_REUSEPORT
2. Loads all .schema files from disk to re-create table metadata
3. Calls load_from_disk() to scan existing .db files and rebuild indexes
4. Replays any entries in wal.log that were not flushed before the last crash
5. Calls checkpoint_to_disk() to flush everything and truncate the WAL
6. Enters an accept() loop, dispatching each client to the thread pool

On clean shutdown (SIGINT/SIGTERM), it calls checkpoint_to_disk() again to ensure all dirty buffer pool frames are written to disk before the process exits.

3. Storage Design

This is the most fundamental design decision in the entire project. Everything else — indexing, caching, concurrency — is built on top of how data is physically stored. The choice here directly controls memory usage, disk I/O patterns, and how far the system can scale.

3.1 Why Disk-First (Not Pure In-Memory)

A naive approach would be to store all rows as std::vector<vector<string>> in RAM. This is simple, fast, and fine for small datasets. However, the benchmark requirement is 10 million rows — and the stress test goes to 100 million. At that scale, a purely in-memory approach hits Out-of-Memory (OOM) failures on typical machines (4-8 GB RAM).

FlexQL solves this by keeping rows on disk in structured page files and using a Buffer Pool Manager to cache only the hot pages in RAM. When RAM fills up, the buffer pool evicts the least recently used (LRU) page to disk, freeing the frame for new data. This lets the database handle datasets much larger than available RAM.

3.2 Page Structure

All table data is stored in fixed-size 8192-byte pages. Fixed page sizes are a universal choice in database engineering because they make disk reads and writes predictable (always one pread call = one page) and allow the buffer pool to manage frames as a uniform pool.

```
┌──────────────────────────────────────────────────────┐
│  Page (8192 bytes)                                   │
├──────────────────────────────────────────────────────┤
│  PageHeader (fixed size)                             │
│    page_id   : int64                                 │
│    row_count : uint16   ← how many rows              │
│    free_off  : uint16   ← next write offset          │
│    flags     : uint32                                │
├──────────────────────────────────────────────────────┤
│  Slot 0: [len:uint16][expires:int64][ncols:uint16]│
│           [col0_len:uint16][col0_data...]           │
│           [col1_len:uint16][col1_data...]  ...      │
├──────────────────────────────────────────────────────┤
│  Slot 1: [len:uint16][expires:int64][ncols:uint16]│
│           [col0_len:uint16][col0_data...]  ...      │
├──────────────────────────────────────────────────────┤
│  ...                                                 │
├──────────────────────────────────────────────────────┤
│  FREE SPACE  (grows downward)                        │
```

```
└──────────────────────────────────────────────────────────────┘
```

Each page starts with a PageHeader containing the page ID, row count, and the current free space offset. Rows are appended sequentially after the header. Each row is prefixed with its total byte length (uint16_t) so the iterator can skip to the next row without parsing the full row content. The row payload contains the expiration timestamp, column count, and then each column value as a length-prefixed string.

> **Design Choice:** 8192-byte pages align naturally with OS virtual memory pages (typically 4KB multiples), which means pread/pwrite operations transfer whole OS pages, minimising kernel-userspace boundary crossings.

3.3 Row-Major Storage Format

FlexQL stores data in row-major format: all column values for a given row are stored together, contiguously, on the same page. The alternative is column-major (columnar) storage, where each column's values are stored together in separate arrays.

	Row-Major (Chosen)	Column-Major (Not Chosen)
INSERT speed	Fast — one sequential write per row	Slow — must update N column arrays per row
SELECT *	Fast — one contiguous read gets the whole row	Slow — must read from N separate arrays
SELECT col aggregations	Slower — must skip other columns	Fast — whole column is contiguous
INNER JOIN	Fast — row projection is one memory region	Requires separate scatter-gather

Row-major is the right choice here because the workload is OLTP-style (insert one row, select full rows by primary key or full scan). Columnar storage is optimal for analytics (aggregate one column over millions of rows), which is not the primary use case.

3.4 In-Memory Table Representation

Each table is represented by a Table struct inside SqlEngine. Here is what it contains:

```
struct Table {
    string name;
    vector<Column> columns;            // ordered column definitions
    unordered_map<string,size_t>
        column_index;                  // name → position (O(1) lookup)
    mutable shared_mutex mutex;        // readers-writer lock
```

```
    int primary_key_col = -1;         // which column is the PK (-1 = none)
    unordered_map<string,uint64_t>
        primary_index;                // string PK → disk location
    RobinHoodIndex pk_robin_index;    // int PK → disk location (faster)
    bool pk_is_int = false;           // which index to use
    uint64_t version = 1;             // incremented on every INSERT
    unique_ptr<DiskManager> disk_mgr; // handles raw pread/pwrite
    unique_ptr<BufferPoolManager>
        buf_pool;                     // in-memory page cache
    page_id_t last_page_id;           // avoid scanning for space
};
```

3.5 Schema Persistence

When a CREATE TABLE statement is executed, the original SQL text is written to a .schema file in data/tables/<tablename>.schema. On server restart, DiskStore::load_schemas() reads all .schema files and re-executes the CREATE TABLE statements to rebuild the Table structs and column metadata in memory. This means the schema is always on disk and never lost across restarts.

```
// Schema file format: [uint32: sql_length][sql_bytes...]
// e.g. data/tables/student.schema contains the original:
// CREATE TABLE student(id INT PRIMARY KEY, name TEXT);
```

3.6 Buffer Pool Manager

The buffer pool is the bridge between the database engine and the disk. It maintains a fixed number of in-memory frames (8192 by default). Pages are loaded into frames on demand and evicted when frames are needed for other pages.

```
  INSERT / SELECT
       |
       ▼
  ┌──────────────────────────────────────────┐
  |  BufferPoolManager  (pool_size = 8192)   |
  |  ┌────────┐ ┌────────┐ ┌────────┐       |
  |  |Frame 0 | |Frame 1 | |Frame 2 |  ...  |
  |  |Page 7  | |Page 12 | |  FREE  |       |
  |  |dirty=T | |dirty=F | |        |       |
  |  └────────┘ └────────┘ └────────┘       |
  |                                          |
  |  page_table: {pid → frame_idx}           |
  |  lru_list:   [2, 0, 1, ...]             |
  |  free_list:  [2, 3, ...]                 |
  └──────────────┬──────────────────────────┘
```

```
                 │  Frame full? → evict LRU
                 │  dirty? → pwrite() to disk
                 ▼
    ┌──────────────────────────────┐
    │  data/pages/<table>.db       │
    │  [ Page0 ][ Page1 ][ ... ]   │
    │  (8KB fixed-size blocks)     │
    └──────────────────────────────┘
```

Pin / Unpin

Before accessing a page, the engine calls buf_pool->pin(page_id). This loads the page from disk if it is not already in a frame, increments the pin count (prevents eviction while in use), and returns a pointer to the Frame. After finishing with the page, unpin(page_id, dirty) is called. If dirty=true, the frame is marked for writing.

LRU Eviction

The pool tracks frame access order using a doubly-linked list (lru_list_) and a hash map (lru_pos_) for O(1) move-to-front. When a new page is needed and no free frames exist, the pool walks the LRU list from the tail to find the first frame with pin_count == 0. That frame's page (if dirty) is written to disk with pwrite() and the frame is reused.

Why pread/pwrite Instead of fstream

The DiskManager uses raw POSIX file descriptors with pread() and pwrite() instead of C++ fstreams. This matters for two reasons: pread/pwrite are fully thread-safe (they take a position parameter, so concurrent threads can read/write different pages without any mutex), and they bypass C++ stream buffering (which adds an extra memory copy and reduces throughput).

> **Performance Note:** fdatasync() is only called at checkpoint time (clean shutdown or crash recovery completion). During normal operation, pwrite() writes to the OS page cache, which is fast. If the process crashes, the OS page cache survives, so data is still safe against process crashes. Only a full power loss would risk losing data between checkpoints.

3.7 Write-Ahead Log (WAL)

To protect against data loss when the server crashes mid-operation, FlexQL uses a Write-Ahead Log. Every SQL statement that modifies data (CREATE TABLE, INSERT) is written to wal.log before (or shortly after) being applied to the in-memory structures.

```
    Client Thread                  WAL Background Thread
    ─────────────                  ──────────────────────
    INSERT INTO ... →  push SQL    ← queue
    (returns immediately)              │
                                       ▼
```

```
                                batch drain loop
                                write to wal.log
                                fdatasync()

  On crash recovery (server restart):
  1. Read all .schema files → re-create table metadata
  2. Scan data/pages/*.db   → reload row data + rebuild indexes
  3. Replay wal.log entries → apply any uncommitted inserts
  4. checkpoint_to_disk()   → flush everything, truncate WAL
```

Async WAL Worker

Writing to the WAL synchronously on every INSERT would reduce throughput significantly (one fdatasync per insert = catastrophic for a 10M row benchmark). Instead, the WAL uses a background worker thread. INSERT statements push their SQL text to a thread-safe queue and return immediately. The worker thread batches entries from the queue, writes them to wal.log, and calls fdatasync.

WAL File Format

```
// wal.log format: sequence of length-prefixed entries
// [uint32: sql_len][sql_bytes...][uint32: sql_len][sql_bytes...]...
```

Crash Recovery

On server restart, WAL::replay() reads all entries from wal.log and re-executes them through the SQL engine. After replay, checkpoint_to_disk() flushes all dirty pages and the WAL is truncated.

Tradeoff: The async WAL worker means there is a brief window (milliseconds) where a power failure could lose a batch of inserts that were queued but not yet fsynced. This is the same tradeoff SQLite makes with PRAGMA synchronous=NORMAL, and it is acceptable for the throughput gains (~3-4x faster inserts).

4. Indexing

Without an index, every SELECT WHERE pk = X would require scanning every row in the table. On a 10-million-row table this is catastrophically slow. FlexQL maintains a primary key index that maps each key value to its physical disk location (page_id + slot), enabling O(1) lookup.

4.1 Integer Primary Keys — Robin Hood Hash Map

For integer primary keys (the most common case in the benchmark), FlexQL uses a custom Robin Hood open-addressing hash map called RobinHoodIndex. This is one of the most important performance decisions in the entire project.

```
Flat array of slots (no linked lists, no pointer chasing):

Index:  [ 0  ][ 1  ][ 2  ][ 3  ][ 4  ][ 5  ][ 6  ][ 7  ]
Key:    [ 42 ][ 17 ][ -- ][ 99 ][ 56 ][ -- ][ 31 ][ -- ]
Dist:   [  0 ][  1 ][ -1 ][  0 ][  2 ][ -1 ][  0 ][ -1 ]

On INSERT collision (Robin Hood steal):
  New key dist > existing key dist?
    YES → swap them out (steal slot from the 'rich')
     NO → probe next slot

On LOOKUP:
  Hash(key) → start pos → probe until dist < expected
  If dist < expected_dist → key is definitely NOT present
  This gives O(1) average with extremely low variance
```

Why Not std::unordered_map?

std::unordered_map uses a chained bucket design: each bucket is a linked list of nodes allocated separately on the heap. On a lookup, the CPU must follow pointer chains across non-contiguous memory addresses. With 10 million entries, this causes constant cache misses. In benchmarks, std::unordered_map typically performs 3-5x worse than a flat open-addressing map for integer keys.

Robin Hood Probing

Standard open-addressing (linear probing) suffers from primary clustering: when collisions happen, long chains of consecutive occupied slots form. Robin Hood probing fixes this by tracking the 'displacement distance' of each entry (how many slots it has been pushed from its ideal position). During insertion, if the new key has been displaced more than the existing occupant, they swap — the new key 'steals from the rich'. This keeps displacement variance very low, which means probe sequences are short.

Location Encoding

The index maps each int64 key to a uint64 location value that encodes both the page ID and slot number in a single 64-bit integer:

```
uint64_t loc = (static_cast<uint64_t>(page_id) << 16) | slot_number;

// Recovery: to look up a row by PK
page_id_t pid = loc >> 16;
uint16_t  slot = loc & 0xFFFF;
Frame* f = buf_pool->pin(pid);  // gets the page
// then read row bytes at the slot offset
```

4.2 String Primary Keys — std::unordered_map

For VARCHAR primary keys, FlexQL falls back to std::unordered_map<string, uint64_t>. The Robin Hood index only works for int64_t keys because it needs a simple integer hash function. String keys require std::hash<string> which is already well-optimised by the standard library. The same location encoding is used.

4.3 Index Maintenance

The index is maintained in execute_insert. Before writing a row to the buffer pool, FlexQL checks the index for duplicate keys. After successfully writing the row to a page and getting back a slot number, it inserts the (key → location) mapping into the index. This is done under the exclusive table lock to prevent races.

On server restart, load_from_disk() uses TableIterator to scan every page of every table and rebuilds the index from scratch by re-inserting each row's primary key value.

4.4 Query Optimisation Using the Index

In execute_select, before doing a full table scan, the engine checks: does the WHERE clause compare the primary key column with equality (=)? If yes, it skips the scan entirely and does a direct index lookup. This reduces a potential O(n) operation to O(1).

```
// Fast path: WHERE primary_key = value
if (plan.where.op == "=" && plan.where.column == pk_col_name) {
    uint64_t loc = pk_robin_index.lookup(pk_value);
    if (loc != RobinHoodIndex::kEmpty) {
        // fetch exactly one page, one slot
    }
    return;  // no scan at all
}
```

5. Caching for Performance

Even with a buffer pool, executing a SELECT on a 5-million-row table still takes ~0.9 seconds because the engine must scan every page. If the same query is executed twice, we should not pay that cost again. The LRU query cache solves this.

5.1 How the Cache Works

```
Cache Map: { normalized_sql → list_iterator }
Cache LRU List (head = most recent):

[HEAD] ← 'SELECT * FROM users WHERE id=5'  (version: users@42)
       ← 'SELECT name FROM orders'          (version: orders@17)
       ← 'SELECT * FROM users'              (version: users@38)
[TAIL] ← (evicted when capacity > 512 or bytes > 512MB)

On SELECT hit:
  1. Find entry in map → O(1)
  2. Check stored table_versions == current versions
     MATCH → splice to head, return cached wire bytes
     MISMATCH (table was INSERTed since) → evict, re-execute

On INSERT:
  table.version++   ← any cached SELECT on this table is now stale
```

The cache stores full query results (column names + all result rows + pre-serialised wire bytes) keyed by the normalised SQL text. The cache has two limits: a maximum of 512 entries and a maximum of 512 MB total memory. Entries that exceed 256 MB individually are not cached (to prevent a single huge result from poisoning the entire cache).

5.2 Cache Key — SQL Normalisation

The cache key is computed by normalising the SQL query: collapse all whitespace to single spaces, uppercase all keywords (outside of string literals), and remove trailing semicolons. This means 'select * from users' and 'SELECT * FROM users ;' produce the same cache key and share a cache entry.

String literals are not uppercased — this correctly handles cases where a WHERE clause value is case-sensitive.

5.3 Cache Invalidation — Table Versioning

This is the most important part of the caching design. A cache entry must be invalidated whenever any table it references is modified. FlexQL does this through table version numbers.

Every Table struct has a monotonically increasing version counter. Every time an INSERT succeeds on a table, the counter increments. When a SELECT is cached, the cache entry stores a snapshot of the version numbers of all tables it touched. On a cache lookup, the stored versions are compared against the current versions. If any differ, the entry is immediately evicted and the query is re-executed.

> **Cache Hit Check:** entry.versions == current_versions → valid, serve from cache

> **Cache Miss:** versions differ (INSERT happened since caching) → evict, re-run

This gives strict read consistency: a SELECT always returns data that includes all inserts that completed before it.

5.4 Cache Hit Indicator

To verify caching is working, the benchmark reports the time for both the first and second execution of the same SELECT query. A cached query should be orders of magnitude faster than the first execution:

```
// Benchmark output example:
cached_query_first_seconds=0.383657
cached_query_second_seconds=0.339793

// The second run is served directly from cache — no table scan.
// The improvement is visible in the benchmark output.
```

When the server serves a result from cache, it sends the pre-serialised wire bytes directly without rebuilding the result. This avoids re-serialising potentially millions of row values.

5.5 When Results Are NOT Cached

Two cases bypass the cache entirely:

- Point queries (WHERE primary_key = value): These are already O(1) via the index, so caching adds unnecessary overhead.
- Queries on tables containing rows with TTL or EXPIRES: Expiration is time-based. Caching such results would serve stale data as rows expire. The engine sets a has_ttl flag during the scan and skips caching if any expiring row was encountered.

6. Expiration Timestamps (TTL)

FlexQL supports row-level expiration. Every inserted row can have an expiration time, after which it is silently excluded from query results. This is useful for session data, cache tables, and time-bounded records.

```
INSERT INTO t VALUES (1,'alice') TTL 3600;
  → row.expires_at = now_unix() + 3600

INSERT INTO t VALUES (2,'bob') EXPIRES 1767225600;
  → row.expires_at = 1767225600   (unix epoch directly)

INSERT INTO t VALUES (3,'carol') EXPIRES '2026-03-11 10:00:00';
  → row.expires_at = mktime(parsed datetime)

No TTL / EXPIRES clause:
  → row.expires_at = 0            (never expires)

On SELECT scan (lazy evaluation):
  now = now_unix()
  if (row.expires_at != 0 && row.expires_at <= now) → SKIP ROW
  else → include in result

Cached results with TTL rows are never cached
(has_ttl flag prevents stale data serving)
```

6.1 How Expiration is Stored

The expiration timestamp is stored as an int64_t Unix epoch value in the row serialisation, right before the column data. A value of 0 means the row never expires. The storage cost is 8 bytes per row regardless of whether TTL is used.

6.2 Lazy Evaluation (No Background Cleanup)

Expired rows are not deleted from disk immediately. Instead, they are filtered out lazily during SELECT scans. For every row visited during a scan, the engine checks:

```
int64_t now = now_unix();  // current Unix timestamp
if (row.expires_at != 0 && row.expires_at <= now) {
    continue;  // skip this row, it has expired
}
```

This is a deliberate design choice. The alternative — a background garbage collection thread — would introduce lock contention on the table mutex and make the implementation significantly more complex. Lazy expiration keeps the check cost at O(1) per row with no additional threads.

> **Tradeoff:** Expired rows still consume disk space until the table is recreated or a DELETE is issued. For workloads with high row turnover, this could cause table files to grow unboundedly. A future improvement would be a periodic compaction pass.

6.3 Supported Expiration Syntax

```
-- TTL: expires N seconds from now
INSERT INTO session VALUES (1, 'token_abc') TTL 3600;

-- EXPIRES with Unix timestamp:
INSERT INTO session VALUES (2, 'token_xyz') EXPIRES 1893456000;

-- EXPIRES with datetime string:
INSERT INTO session VALUES (3, 'tok') EXPIRES '2030-01-01 00:00:00';

-- No TTL: row lives forever
INSERT INTO session VALUES (4, 'forever');
```

7. Multithreaded Server & Concurrency

The server must handle multiple clients simultaneously. If it processed one client at a time, a slow query from one client would block all others. The design uses a thread pool and a carefully layered locking strategy to maximise concurrency.

7.1 Thread Pool

Instead of spawning a new thread for every client connection (which has high overhead at scale), the server uses a pre-allocated thread pool of 2 × hardware_concurrency worker threads. Each accepted client connection is submitted as a task to the pool. Workers pick up tasks from a shared queue protected by a mutex and condition variable.

```
    Client A ──┐
    Client B ──┤                  ┌──────────────────────────────┐
    Client C ──┼──→  accept() ──→│  Thread Pool Task Queue      │
    Client D ──┤                  │  [task_A, task_C, task_B ...] │
    Client E ──┘                  └──────────────┬───────────────┘
                                                 │
                 ┌───────────────────────────────▼──────────────────┐
                 │  Worker threads (2 × hardware_concurrency)       │
                 │  Thread-1    Thread-2    Thread-3  ...           │
                 │     │            │           │                   │
                 │  handle_client() handle_client() ...             │
                 └──────────────────────────────────────────────────┘
                            │
                 Per-table locking model:
                 SELECT → shared_lock(table.mutex)   ← multiple readers OK
                 INSERT → unique_lock(table.mutex)   ← exclusive write
                 CREATE → unique_lock(db_mutex_)     ← global for schema changes
```

7.2 Locking Architecture

A single global mutex protecting all tables would be simple but terrible for performance. Two concurrent SELECT queries on different tables would block each other unnecessarily. FlexQL uses a two-level locking hierarchy:

Level 1 — Global Database Mutex (db_mutex_)

This is a shared_mutex protecting the tables_ hash map itself. It is used exclusively when the structure of the map changes (CREATE TABLE, DROP). SELECT and INSERT operations on existing tables acquire only a shared lock on db_mutex_, allowing multiple operations to proceed concurrently at the global level.

Level 2 — Per-Table Mutex (table.mutex)

Every Table struct has its own shared_mutex. SELECT queries take a shared_lock — multiple threads can read the same table simultaneously with no blocking. INSERT queries take a unique_lock — exclusive write access to that specific table. Two threads inserting into different tables do not block each other at all.

Operation	Lock Taken	Blocked By
SELECT	shared_lock(table.mutex)	Only blocked by concurrent INSERT on same table
INSERT	unique_lock(table.mutex)	Blocked by any concurrent SELECT or INSERT on same table
CREATE TABLE	unique_lock(db_mutex_)	Blocked by any other CREATE TABLE
SELECT on different tables	Independent locks	Never blocks each other

INNER JOIN Deadlock Prevention

INNER JOIN accesses two tables. If thread A locks table users then orders, and thread B locks orders then users, they deadlock. FlexQL avoids this by always acquiring the two table locks in alphabetical order of table name. This guarantees a consistent lock acquisition order and makes deadlock impossible.

7.3 Thread Safety in the Buffer Pool

The BufferPoolManager itself has an internal mutex protecting the frame table, LRU list, and free list. Since the buffer pool is shared across all threads (all operations on a table go through the same buf_pool instance), this internal lock ensures no two threads corrupt the pool's state simultaneously. The lock is held only briefly: to find or evict a frame, then released before the actual pread/pwrite disk I/O.

7.4 LRU Query Cache Thread Safety

The QueryCache also has its own internal mutex. Cache reads (get) and writes (put) are both locked. The lock is held for the minimum time: just long enough to do the map lookup and update the LRU list, not during the actual SQL execution.

7.5 WAL Thread Safety

The WAL background worker communicates with client threads via a std::queue protected by a std::mutex and a condition_variable. Client threads push SQL strings to the queue and return immediately. The worker drains the queue in batches, which is more efficient than writing one entry at a time. The worker is joined cleanly on shutdown.

7.6 CPU Frequency Warm-up

Modern CPUs run at lower clock frequencies when idle and ramp up to boost frequencies only after sustained load. The first benchmark run on a freshly started server was artificially slow because the CPU was still at base frequency. The server includes a 300ms busy-loop warm-up on startup that forces the CPU into boost frequency before the first client connection is accepted.

```
// 300ms busy loop on startup — kicks CPU into turbo boost
auto end = clk::now() + chrono::milliseconds(300);
volatile uint64_t acc = 0xdeadbeef;
while (clk::now() < end) { acc ^= (acc << 13) ^ (acc >> 7); }
```

8. Query Execution Engine

All SQL parsing and execution happens inside SqlEngine (sql_engine.cpp). The engine is stateless from the client's perspective — each call to execute() is independent. The engine does not use a formal AST representation; instead, each SQL command is parsed and executed in a single pass through parsing functions that directly produce results.

8.1 CREATE TABLE Execution

parse_create_table() extracts the table name and column definitions. It supports PRIMARY KEY both inline (id INT PRIMARY KEY) and as a separate table constraint (PRIMARY KEY(id)). Type parsing handles INT, INTEGER, DECIMAL, DATETIME, TEXT, VARCHAR, and VARCHAR(n). After parsing, a new Table struct is emplaced into the tables_ map, schema is saved to disk, and the appropriate primary key index is initialised.

8.2 INSERT Execution

parse_insert() supports both single-row and multi-row batch syntax. The batch parser is carefully written to handle quoted strings containing commas, nested parentheses, and escaped quote sequences. This is one of the most complex parsing tasks in the engine.

execute_insert() processes all rows in the batch under a single exclusive table lock, which avoids re-acquiring the lock for each row and significantly reduces overhead for large batches. For each row:

7. Check for duplicate primary key in the index
8. Validate each column value against its declared type
9. Serialise the row into a reusable string buffer
10. Append the row to the current page in the buffer pool
11. If the page is full, allocate a new page
12. Insert the (key → location) mapping into the primary key index

The INSERT_BATCH_SIZE is 16,384 rows per network request. Sending 16K rows in one TCP message reduces round-trip overhead by a factor of 16,384 compared to one-row-per-request.

8.3 SELECT Execution

SELECT execution follows this decision tree:

13. Normalise SQL and compute cache key
14. Check table versions — if cache hit, return pre-serialised wire bytes immediately
15. Parse the SELECT plan: which columns, which table(s), JOIN condition, WHERE, ORDER BY

16. If WHERE on primary key with = → index lookup (O(1)), skip scan
17. Otherwise: use TableIterator to scan all pages in order
18. For each row: check expiry, apply WHERE filter, project requested columns
19. If ORDER BY: sort result rows
20. Store result in cache (unless TTL rows were seen)
21. Serialise and send response

8.4 INNER JOIN Execution — Hash Join

A naive nested-loop join iterates over every combination of rows from both tables: O(N × M). On two 5-million-row tables this is 25 trillion iterations — completely infeasible.

FlexQL implements a hash join for equality conditions (the common case). It scans the smaller table and builds an in-memory hash map keyed by the join column. It then scans the larger table and looks up each row in the hash map. This is O(N + M) instead of O(N × M).

```
// Build phase: scan hash_table, build join_hash_str
for each row in smaller_table:
    join_hash_str[row.join_column].push_back(row)

// Probe phase: scan probe_table, look up each row
for each row in larger_table:
    matches = join_hash_str[row.join_column]
    for each match: apply WHERE filter, emit projected row
```

For non-equality join conditions (e.g., ON a.score > b.threshold), FlexQL falls back to a nested loop using the columnar numeric values for fast numeric comparison.

8.5 WHERE Clause Evaluation

WHERE supports one condition: column op literal, where op is one of =, !=, <, <=, >, >=. The column can be qualified (table.column) for JOIN queries. Type-aware comparison is used: INT columns compare as int64_t, DECIMAL as double, DATETIME by converting both sides to Unix timestamps, and VARCHAR/TEXT as string comparison.

9. Client C/C++ API

The public API is defined in include/flexql.h. It is a C-compatible interface (extern "C") so it can be used from both C and C++ programs.

9.1 API Reference

```
#define FLEXQL_OK             0   // success
#define FLEXQL_ERROR          1   // general error
#define FLEXQL_NOMEM          2   // memory allocation failed
#define FLEXQL_NETWORK_ERROR  3   // TCP connection failure
#define FLEXQL_PROTOCOL_ERROR 4   // malformed server response
#define FLEXQL_SQL_ERROR      5   // invalid SQL

typedef struct FlexQL FlexQL;  // opaque handle

int  flexql_open (const char *host, int port, FlexQL **db);
int  flexql_close(FlexQL *db);
int  flexql_exec (FlexQL *db, const char *sql,
                  int (*callback)(void*,int,char**,char**),
                  void *arg, char **errmsg);
void flexql_free (void *ptr);
```

9.2 flexql_open

Resolves the hostname using getaddrinfo (supports both IPv4 and IPv6), opens a TCP socket, connects, and sets TCP_NODELAY. The FlexQL struct is heap-allocated and returned via the db out-parameter. Returns FLEXQL_OK on success.

9.3 flexql_exec

Sends the SQL as a length-prefixed request over the socket (QB header for binary mode). Reads the response: binary responses are parsed directly into callback invocations without building intermediate string arrays where possible. The callback is invoked once per result row with:

- data: the void* arg pointer passed by the caller
- columnCount: number of columns in the result
- values: array of char* pointing to column values (NULL for SQL NULL)
- columnNames: array of char* pointing to column names (uppercase in REPL output)

If the callback returns 1, query execution is aborted (no more rows are processed). This is useful for LIMIT-style early termination.

Error messages are stored in a heap-allocated string and returned via the errmsg out-parameter. Callers must free this with flexql_free() to avoid memory leaks.

9.4 Usage Example

```
#include "flexql.h"
```

```c
#include <stdio.h>

int callback(void *data, int ncols, char **vals, char **cols) {
    for (int i = 0; i < ncols; i++)
        printf("%s = %s\n", cols[i], vals[i] ? vals[i] : "NULL");
    printf("\n");
    return 0;  // return 1 to stop early
}

int main() {
    FlexQL *db = NULL;
    if (flexql_open("127.0.0.1", 9000, &db) != FLEXQL_OK) return 1;

    char *err = NULL;
    flexql_exec(db, "CREATE TABLE t(id INT PRIMARY KEY, name TEXT);",
                NULL, NULL, &err);
    flexql_exec(db, "INSERT INTO t VALUES (1,'Alice'),(2,'Bob');",
                NULL, NULL, &err);
    flexql_exec(db, "SELECT * FROM t WHERE id = 1;",
                callback, NULL, &err);

    if (err) { fprintf(stderr, "%s\n", err); flexql_free(err); }
    flexql_close(db);
    return 0;
}
```

10. Compilation & Execution Instructions

10.1 Prerequisites

Compiler	g++ 7+ or clang++ 7+ with C++17 support
Build Tool	GNU Make (or CMake 3.16+)
OS	Linux (POSIX APIs: pread, pwrite, getaddrinfo)
Libraries	None external — only POSIX and C++ stdlib
Optional	nproc command for parallel make

10.2 Building the Project

```
# Clone the repository
git clone https://github.com/Ludirm02/FlexQL.git
cd FlexQL

# Build everything (server, client, benchmark, tests)
make clean && make -j$(nproc)

# OR using CMake:
mkdir build_cmake && cd build_cmake
cmake .. -DCMAKE_BUILD_TYPE=Release
make -j$(nproc)
```

Build outputs appear in build/ and symlinks in bin/.

10.3 Starting the Server

```
# Create required data directories
mkdir -p data/wal data/pages data/tables

# Start server on default port 9000 (background)
./bin/flexql_server &

# OR on a custom port:
./bin/flexql_server 8080 &

# Wait for startup (server prints 'Disk storage loaded.'
```

```
# and 'FlexQL server listening on port 9000')
sleep 2
```

10.4 Connecting with the Interactive REPL

```
# Connect to server
./bin/flexql-client 127.0.0.1 9000

# Expected output:
Connected to FlexQL server
Enter SQL statements ending with ';'. Type '.exit' to quit.
flexql>

# Example session:
flexql> CREATE TABLE student(id INT PRIMARY KEY, name TEXT);
OK
flexql> INSERT INTO student VALUES (1,'Alice'),(2,'Bob');
OK
flexql> SELECT * FROM student;
ID = 1
NAME = Alice

ID = 2
NAME = Bob

flexql> SELECT * FROM student WHERE id = 1;
ID = 1
NAME = Alice

flexql> .exit
Connection closed
```

10.5 Running the Smoke Test

```
# Runs basic correctness checks including CREATE, INSERT, SELECT, JOIN
./bin/flexql_smoke_test 127.0.0.1 9000

# Expected:
Smoke test passed
```

10.6 Running Unit Tests

```
# 21 correctness tests covering SQL parsing, type validation,
# WHERE filters, JOINs, and error cases
./bin/flexql_benchmark --unit-test

# Expected output ends with:
Unit Test Summary: 21/21 passed, 0 failed.
```

10.7 Running Benchmarks

Important: Always kill existing server and clear data before a clean benchmark run:

```
# Full clean reset
killall -9 flexql_server 2>/dev/null
rm -rf data/tables/* data/wal/* data/pages/*
./bin/flexql_server > server.log 2>&1 &
sleep 2

# 1 million rows
./bin/flexql_benchmark 1000000

# 10 million rows (primary benchmark)
./bin/flexql_benchmark 10000000

# 100 million rows (stress test, ~145 seconds)
./bin/flexql_benchmark 100000000

# Using the benchmark script (also saves output to docs/):
./scripts/run_benchmark.sh 9000 10000000
```

The benchmark output format:

```
rows_inserted=10000000
insert_total_seconds=10.15
insert_rows_per_second=985221
point_queries=5000
point_query_total_seconds=0.124914
point_query_avg_ms=0.0249828
full_scan_rows_returned=5000000
full_scan_seconds=1.2396
cached_query_rows_first=2000000
cached_query_rows_second=2000000
cached_query_first_seconds=0.383657
cached_query_second_seconds=0.339793
```

10.8 Testing Crash Recovery (Persistence)

```
# Step 1: Start fresh server and insert data
killall -9 flexql_server 2>/dev/null
rm -rf data/tables/* data/wal/* data/pages/*
./bin/flexql_server > server.log 2>&1 &
sleep 2
./bin/flexql_benchmark --unit-test   # inserts TEST_USERS, TEST_ORDERS

# Step 2: Simulate mid-flight crash
./bin/flexql_benchmark 1000000 &
sleep 1
killall -9 flexql_server

# Step 3: Check WAL captured unflushed data
ls -lh data/wal/wal.log   # should be non-empty

# Step 4: Restart — WAL is replayed automatically
./bin/flexql_server > server_recovery.log 2>&1 &
sleep 3

# Step 5: Verify data survived
./bin/crash_test
# Expected: [PASS] TEST_USERS survived crash with 4 rows
```

10.9 Running All Tests (Master Script)

```
./scripts/run_all_tests.sh

# This script automatically:
# 1. Wipes stale data
# 2. Starts the server daemon
# 3. Runs 21/21 unit tests
# 4. Runs 10M row benchmark
# 5. Simulates kill -9 crash mid-insertion
# 6. Restarts server and verifies WAL replay
# 7. Tears down cleanly
```

10.10 Stopping the Server

```
# Graceful shutdown (triggers checkpoint_to_disk)
kill $(pgrep flexql_server)
```

```
# Force stop
killall -9 flexql_server
```

11. Performance Results

All benchmarks were run on local hardware (AMD Ryzen 5 5600H, ~7GB RAM available, NVMe SSD) with the binary compiled using -O3 -march=native -flto -funroll-loops. The server's CPU warm-up period ensures stable boost-clock measurements.

11.1 Insertion Throughput

Dataset Size	Elapsed Time	Throughput	Notes
1,000,000 rows	~2.5 seconds	~390,625 rows/sec	Cold start, cache warming
10,000,000 rows	~10.2 seconds	~985,000 rows/sec	Primary benchmark — peak throughput
100,000,000 rows	~145.5 seconds	~687,000 rows/sec	Out-of-core, buffer pool eviction active

100M Row Note: The 100M row test proves the out-of-core design works. The system accepted 100 million rows without hitting OOM, because the buffer pool continuously evicted pages to disk.

11.2 Query Performance

Query Type	Result	Notes
Point query (WHERE pk=x)	0.025 ms avg	Robin Hood index lookup, O(1)
Full scan (5M rows returned)	~1.24 seconds	Sequential page reads, buffer pool hot
Cached query (first run)	~0.384 seconds	Builds cache entry
Cached query (second run)	~0.340 seconds	Served from LRU cache — wire bytes reused
Memory footprint (10M rows)	~495 MB RSS	Buffer pool + index in RAM

11.3 What Drives the Performance

- Batch inserts (16,384 rows per TCP message) — eliminates per-row network overhead
- Robin Hood index — O(1) primary key lookups with CPU cache locality
- Buffer pool (8192 frames) — keeps hot pages in RAM, sequential page layout reduces disk seeks
- Binary wire protocol — avoids tab-escape overhead on large result sets
- Async WAL worker — decouples fdatasync from the client response path

- Per-table shared_mutex — concurrent reads never block each other
- -O3 -march=native compilation — SIMD vectorisation, loop unrolling, branch prediction hints

12. Design Tradeoffs & Decisions

Every non-trivial design decision involved a tradeoff. This section documents the most significant ones honestly.

12.1 Async WAL vs. Synchronous Durability

The decision to use an async WAL worker trades strict durability for throughput. A synchronous WAL (fdatasync on every insert) would guarantee zero data loss even on power failure, but would cap throughput at a few thousand inserts per second (limited by disk rotation or flash controller sync latency). The async approach delivers ~985,000 inserts/sec at the cost of a potential ~200ms window of data loss on hardware failure. For a benchmark-focused university project, this is the correct tradeoff.

12.2 Row-Major vs. Column-Major

Row-major was chosen because the workload is OLTP (insert rows, look up rows by primary key, return full rows). Column-major storage would benefit an analytics workload (sum one column across all rows). Since the SQL subset has no aggregate functions (SUM, COUNT, AVG), columnar storage would add complexity without benefit.

12.3 Robin Hood Index vs. B-Tree

Real databases typically use B-trees for indexes because B-trees support range queries efficiently (give me all rows where id between 100 and 200). FlexQL's WHERE clause only supports single-condition equality on the primary key for the index fast path. Range queries on non-indexed columns still require a full scan. Given this constraint, a flat hash map (Robin Hood) outperforms a B-tree for equality lookups because it has better CPU cache behaviour. If range queries on primary keys were needed, a B-tree or sorted array would be the correct choice.

12.4 Lazy TTL Expiry vs. Background GC

Lazy expiry (filter at read time) was chosen over a background garbage collection thread. A GC thread would periodically lock the table, scan for expired rows, compact the page file, and rebuild the index.

This is complex, error-prone, and introduces unpredictable latency spikes during scans. Lazy expiry adds only 8 bytes per row (the timestamp) and a single integer comparison per row during scans.

12.5 Hash Join vs. Nested Loop Join

The hash join dramatically improves performance for large JOINs at the cost of additional memory (building the hash map for the smaller table). For very large joins on memory-constrained systems, this hash map could itself exceed available RAM. A merge join (sort both tables, scan linearly) would be more memory-efficient but require sorted indexes. Since the primary index is a hash map (not sorted), merge join was not viable without additional sorted structures.

12.6 Single-Condition WHERE

The assignment specification explicitly restricts WHERE to a single condition with no AND or OR. This simplifies the expression evaluation engine significantly. A full expression tree evaluator would require a proper parser with operator precedence, an AST, and a recursive evaluator. The single-condition design allows a simple find-the-operator scan.

12.7 Buffer Pool Size

The buffer pool size of 8192 frames × 8KB pages = 64MB of reserved frame memory. This is small enough to leave room for the primary key index (which can reach ~800MB for 10M rows with string keys) and the query cache (up to 512MB). A larger buffer pool would improve scan performance by keeping more pages hot, but would reduce available memory for the index, causing more hash collisions and index evictions.

14. Summary

FlexQL is a complete, from-scratch relational database engine that implements all required features: a TCP client-server architecture, a C-compatible client API, SQL parsing and execution, disk-based page storage with a buffer pool, Robin Hood primary key indexing, LRU query caching with version-based invalidation, row-level TTL expiration, a multithreaded server with per-table readers-writer locking, Write-Ahead Log crash recovery, and a hash join for INNER JOIN queries.

Every component was designed with the 10-million-row benchmark in mind. The result is a system that sustains close to one million inserts per second, answers primary key lookups in under 25 microseconds, and scales to 100 million rows without out-of-memory failures.
