FlexQL

High-Performance SQL-like Database Engine

Design Document

Repository	https://github.com/Ludirm02/FlexQL
Language	C++17 — zero external database libraries
Architecture	Multithreaded TCP client-server + disk buffer pool
Peak Throughput	~985,000 rows/sec (10 million row benchmark)
Out-of-Core	100 million rows with no OOM — buffer pool eviction
Crash Recovery	Write-Ahead Log + schema + page persistence
Index Type	Robin Hood open-addressing hash map (INT PKs)
Cache Strategy	LRU query cache + table-version invalidation

1. What Is FlexQL?

FlexQL is a custom, high-performance, SQL-like relational database engine written entirely in C++17. It was designed and built from scratch — no SQLite, no RocksDB, no libpq, no external database library of any kind was used. Every single component — from the SQL parser and query executor to the disk manager, buffer pool, WAL, indexing structures, caching layer, and TCP wire protocol — was implemented by hand.

The system is modelled as a traditional client-server database. A long-running server process owns all the data and executes SQL queries sent to it by one or more clients over a TCP connection. Clients interact through a C-compatible API (flexql.h) that mirrors the ergonomics of SQLite's callback-based interface. An interactive REPL terminal is also provided for manual use.

The central engineering challenge FlexQL was designed around is scale. An in-memory database is fast but collapses the moment data exceeds physical RAM. FlexQL addresses this by implementing a real page-based storage engine backed by a disk buffer pool with LRU eviction, so datasets of 100 million rows or more can be handled without an out-of-memory crash. At the same time, the system reaches over 985,000 insertions per second on standard hardware through a combination of batch inserts, async WAL writes, a custom Robin Hood hash index, an LRU query cache, and aggressive compiler optimizations.

1.1 Full Feature Set

SQL commands supported:

- CREATE TABLE with INT, DECIMAL, VARCHAR(n), TEXT, and DATETIME column types — PRIMARY KEY both inline and as a table-level constraint, NOT NULL
- INSERT INTO ... VALUES (...) with single-row and multi-row batch support (16,384 rows per statement in benchmark)
- Row expiration via TTL <seconds> or EXPIRES <unix_timestamp> or EXPIRES '<datetime string>'
- SELECT *, SELECT col1, col2 — with optional single-condition WHERE and optional ORDER BY col [ASC | DESC]
- INNER JOIN ... ON ... — equality and range join conditions, optional WHERE on joined result
- DELETE FROM table — drops all rows, resets index and buffer pool, preserves schema
- Primary key indexing with O(1) lookups via Robin Hood hashing for INT PKs
- LRU query result cache with version-based invalidation and pre-built wire bytes
- Concurrent multi-client access with two-level per-table reader-writer locking
- Disk persistence with crash recovery via WAL replay

1.2 Repository & Quick Links

Source Code	https://github.com/Ludirm02/FlexQL
Language	C++17 (compiled with -O3 -march=native -flto)
Build System	GNU Make + CMake (both supported)
Server Binary	bin/flexql_server
Client Binary	bin/flexql-client
Benchmark	bin/flexql_benchmark
Default Port	9000 (configurable via argv)

1.3 What FlexQL Supports

SQL commands supported:

- CREATE TABLE with INT, DECIMAL, VARCHAR(n), TEXT, DATETIME column types and PRIMARY KEY constraints
- INSERT INTO ... VALUES (...) with multi-row batch syntax and optional TTL / EXPIRES clauses
- SELECT * FROM table and SELECT col1, col2 FROM table with optional WHERE and ORDER BY
- WHERE clause with a single condition using =, !=, <, <=, >, >= operators
- INNER JOIN between two tables with an ON condition and optional WHERE filter
- DELETE FROM table (full table clear, resets data and index)

Client API:

- flexql_open(host, port, &db) — connect to server
- flexql_exec(db, sql, callback, arg, &errmsg) — execute any SQL statement
- flexql_close(db) — disconnect and free resources
- flexql_free(ptr) — free memory allocated by the API

2. System Architecture Overview

The diagram below shows every major component of FlexQL and exactly how they connect. Read it top to bottom: the user's code or REPL sits at the top, then the client library, then the TCP boundary, then the server thread pool, then the SQL engine with its cache and index, then the buffer pool, and finally raw disk storage.

```

2.1 Client Side

The client side has two entry points: the REPL and the C API. Both ultimately call the same underlying functions in flexql_client.cpp.

REPL (repl_main.cpp)

The REPL is a simple interactive terminal. It reads lines from stdin, accumulates them until a semicolon is found (supporting multi-line SQL), then calls flexql_exec. Results are printed in the format 'COLUMN_NAME = value'. Typing .exit or .quit disconnects cleanly.

C API (flexql_client.cpp)

This is what user programs link against. It implements the four required functions. Internally it opens a TCP socket, sends queries using the wire protocol, reads the response, and invokes the callback function once per result row. The FlexQL struct is kept opaque — callers only ever hold a pointer to it and never inspect its internals.

```
struct FlexQL {         // Internal — hidden from callers
    int fd;             // TCP socket file descriptor
};
```

```
// Public API — all callers see is the typedef:
typedef struct FlexQL FlexQL;
```

2.2 Wire Protocol

The client and server communicate over a custom binary/text hybrid protocol. There are two modes: a text mode (used by the REPL for human-readable debugging) and a binary mode (used when flexql_exec sends a QB header). Binary mode avoids all tab-escape overhead and is significantly faster for large result sets.

```
Client → Server  (Text mode):        Client → Server  (Binary mode):
──────────────────────────────       ──────────────────────────────
Q <len>\n                            QB <len>\n
<sql bytes>                          <sql bytes>

Server → Client  (Text response):    Server → Client  (Binary response):
─────────────────────────────────    ──────────────────────────────────
OK <ncols>\n                         0x01 [OK frame]
COL\tcol1\tcol2\t...\n              uint32: ncols
ROW\tval1\tval2\t...\n              uint32: nrows
ROW\tval1\tval2\t...\n              [uint16: col_name_len][col_name]...
END\n                               [uint32: val_len][val_bytes]...

Error (text):                        Error (binary):
ERR\t<escaped message>\n            0x02 [ERROR frame]
                                     uint32: msg_len
                                     [message bytes]
```

TCP_NODELAY is set on every socket to eliminate Nagle's algorithm delays. Socket send and receive buffers are tuned to 16MB each to handle large result sets without stalling.

2.3 Server Side

The server (server_main.cpp) does the following on startup:

1. Creates a TCP server socket, sets SO_REUSEADDR and SO_REUSEPORT
2. Loads all .schema files from disk to re-create table metadata
3. Calls load_from_disk() to scan existing .db files and rebuild indexes
4. Replays any entries in wal.log that were not flushed before the last crash
5. Calls checkpoint_to_disk() to flush everything and truncate the WAL
6. Enters an accept() loop, dispatching each client to the thread pool

On clean shutdown (SIGINT/SIGTERM), it calls checkpoint_to_disk() again to ensure all dirty buffer pool frames are written to disk before the process exits.

2.4 Life of a Single INSERT — End to End

Tracing one INSERT query through every component is the clearest way to understand how all pieces connect:

```
flexql_exec(db, "INSERT INTO users VALUES (1,'alice',92.5);", ...)
     │
     ▼  flexql_client.cpp
Send: QB 44\n<44 bytes of SQL>  over TCP
     │
     ▼  Thread pool worker receives bytes
engine->execute(sql, ...)   ← calls SqlEngine::execute()
     │
     ▼  SqlEngine detects INSERT keyword
shared_lock(db_mutex_)      ← look up table name (safe concurrently)
unique_lock(table.mutex)    ← exclusive write access to THIS table
     │
     ├─ validate_typed_value() for each column
     ├─ check Robin Hood index for duplicate PK
     │
     ▼  serialize row
[expires_at:8][ncols:2][col0_len:2][col0_data]...
     │
     ▼  buffer pool
buf_pool->pin(last_page_id)  → Frame*
page.append(serialized_row)  → slot number
if page full → buf_pool->new_page(new_pid)
     │
     ▼  update index
loc = (page_id << 16) | slot
pk_robin_index.insert(pk_int_val, loc)
     │
     ├─ table.version++       ← invalidates LRU cache entries
     ├─ WAL::log(sql)         ← async push to WAL queue (non-blocking)
     │
     ▼  release locks
unique_lock released, shared_lock released
     │
     ▼  server sends response
"OK 0\nEND\n"   over TCP
     │
     ▼  flexql_exec() returns FLEXQL_OK
```

2.5 Life of a Single SELECT — End to End

```
flexql_exec(db, "SELECT * FROM users WHERE score >= 90;", callback, ...)
     │
     ▼  parse_select() → SelectPlan
base_table = "users",  where = {score, >=, 90},  select_star = true
```

```
        |
        ▼  cache check
cache_key = normalize_sql(sql)  →  "SELECT * FROM USERS WHERE SCORE >= 90"
capture table versions:  {users: 42}
cache.get(key, versions) → HIT? serve pre-built wire bytes immediately
                         → MISS? proceed to execution
        |
        ▼  WHERE analysis
Is WHERE on primary key with "="?
  YES → Strategy 1: Robin Hood index lookup (O(1))
  NO  → Strategy 2: Full scan via TableIterator
        |
        ▼  Strategy 2: TableIterator scan
for page_id = 0 to num_pages-1:
  frame = buf_pool->pin(page_id)
  for each row in page:
    if !row_alive(row, now_ts): skip  ← TTL check
    if !evaluate_where(row, condition): skip
    project requested columns → push to out.rows
  buf_pool->unpin(page_id, false)
        |
        ▼  cache store
if no TTL rows: cache.put(key, result, versions)
                → stores wire_bytes + wire_bytes_bin
        |
        ▼  send response
OK 3\nCOL\tid\tname\tscore\nROW\t1\talice\t92.5\nEND\n
```

2.6 Server Startup Sequence

The server does significant work before accepting its first client. This sequence guarantees that after a crash or clean shutdown, all previously committed data is fully recovered and indexed before any new queries are processed:

```
$ ./bin/flexql_server 9000
|
├── 1. Socket setup: socket() + SO_REUSEADDR + SO_REUSEPORT + bind() + listen()
|
├── 2. Load schemas: read data/tables/*.schema
|       re-execute each CREATE TABLE SQL through SqlEngine
|       → rebuilds all Table structs, column metadata, index structures
|
├── 3. load_from_disk(): scan each table's .db file
|       TableIterator walks every page 0..num_pages-1
|       deserializes each row, inserts PK into Robin Hood / string index
|       sets last_page_id = num_pages - 1
|
├── 4. WAL::replay("data/wal/wal.log")
|       reads [len][sql] records, re-executes through SqlEngine
|       (recovers inserts that were in WAL but not yet flushed to pages)
|
```

```
    ├── 5. checkpoint_to_disk()
    │       flush all dirty buffer pool pages + fdatasync each .db file
    │
    ├── 6. Truncate wal.log → WAL::open() for fresh appending
    │
    ├── 7. CPU warm-up: 300ms busy-loop to force turbo-boost frequency
    │
    └── 8. Enter accept() loop → dispatch to thread pool
           'FlexQL server listening on port 9000'
```

3. Storage Design

Storage design is the most fundamental architectural decision in the project. Everything else — indexing, caching, concurrency, recovery — is built on top of how bytes are laid out on disk. The choice here directly determines memory usage, I/O patterns, and how far the system scales.

3.1 Why Disk-First (Not Pure In-Memory)

The simplest database stores every row in a std::vector<Row> in RAM. This is fast to implement and fast to query. The hard limit is physical memory: 10 million rows with 5 string columns each takes approximately 500 MB to 1 GB of RAM. 100 million rows exhausts the memory of most developer machines and the process is killed by the OS OOM killer.

FlexQL was designed to avoid this wall entirely. All data lives on disk in binary page files. Only the pages that are actively needed sit in RAM inside a fixed-size buffer pool. When the pool fills up, cold pages are evicted to disk automatically. This means the amount of data FlexQL can store is bounded only by disk space — exactly how PostgreSQL (shared_buffers), InnoDB (buffer pool), and SQLite (WAL mode) work internally.

3.2 Page-Based Storage — Fixed 8 KB Pages

Every table's data is stored in a single flat file: data/pages/<table_name>.db. This file is divided into fixed-size 8 KB pages (PAGE_SIZE = 8192 bytes). Pages are numbered from 0 and stored consecutively:

```
data/pages/users.db:
  ┌──────────────┬──────────────┬──────────────┬──────────────┐
  │   Page  0    │   Page  1    │   Page  2    │   Page  3    │
  │  8192 bytes  │  8192 bytes  │  8192 bytes  │  8192 bytes  │
  └──────────────┴──────────────┴──────────────┴──────────────┘

  To read page 5:  offset = 5 × 8192 = 40,960 bytes
  pread(fd, buf, 8192, offset)  — one syscall, no seeking
```

Why 8 KB? The Linux virtual memory page size is 4 KB. An 8 KB database page aligns to exactly 2 VM pages — a reasonable tradeoff between the number of frames the buffer pool needs (fewer, larger pages means smaller pool metadata overhead) and the granularity of I/O (smaller pages mean more precise eviction, but more metadata per frame). PostgreSQL uses 8 KB by default for the same reason.

> **Thread Safety:** pread() and pwrite() are position-independent POSIX calls — they take an explicit file offset parameter and never move a file pointer. Multiple threads can call pread/pwrite on the same file descriptor for different page offsets simultaneously with complete safety. No mutex is needed at the file layer.

```
┌──────────────────────────────────────────────────────┐
│  Page (8192 bytes)                                   │
├──────────────────────────────────────────────────────┤

└──────────────────────────────────────────────────────┘
```

Each page starts with a PageHeader containing the page ID, row count, and the current free space offset. Rows are appended sequentially after the header. Each row is prefixed with its total byte length (uint16_t) so the iterator can skip to the next row without parsing the full row content. The row payload contains the expiration timestamp, column count, and then each column value as a length-prefixed string.

> **Design Choice:** 8192-byte pages align naturally with OS virtual memory pages (typically 4KB multiples), which means pread/pwrite operations transfer whole OS pages, minimising kernel-userspace boundary crossings.

3.3 Page Internal Layout

Each page begins with a fixed PageHeader that occupies the first 16 bytes:

```
struct PageHeader {
    page_id_t page_id;   // int64  — 8 bytes — which page number this is
    uint16_t  row_count; // 2 bytes — number of rows stored in this page
    uint16_t  free_off;  // 2 bytes — byte offset where the next row will go
    uint32_t  flags;     // 4 bytes — reserved, currently unused
};
```

After the header, rows are written one after another in the remaining 8176 bytes. Each row entry is preceded by a 2-byte uint16_t length field so the page scanner can skip forward correctly without parsing row internals:

```
┌──────────────────────────────────────────────────────────────────┐
│  Page (8192 bytes total)                                         |
```

```
├──────────────────────────────────────────────────────────────────────┤
│  PageHeader (16 bytes)                                               │
│    page_id   : int64   = 5         ← page number                    │
│    row_count : uint16  = 38        ← rows on this page              │
│    free_off  : uint16  = 7100      ← next write offset              │
│    flags     : uint32  = 0         ← reserved                       │
├──────────────────────────────────────────────────────────────────────┤
│  Slot 0:  [row_len: uint16 = 186][expires_at:int64][ncols:u16]  │
│             [col0_len:u16][col0_data]...[colN_len:u16][colN_data]│
├──────────────────────────────────────────────────────────────────────┤
│  Slot 1:  [row_len: uint16 = 192][expires_at:int64][ncols:u16]  │
│             [col0_len:u16][col0_data]...[colN_len:u16][colN_data]│
├──────────────────────────────────────────────────────────────────────┤
│  ...  (38 rows total)                                                │
├──────────────────────────────────────────────────────────────────────┤
│  FREE SPACE (1092 bytes remaining)  ← next append goes here      │
└──────────────────────────────────────────────────────────────────────┘
```

The scanner reads row_len, advances past row_len bytes, reads the next row_len, and so on — simple forward iteration with zero pointer chasing. The slot number within a page is simply the sequential index of the row (0, 1, 2...) and is used in the primary key location encoding.

3.4 Row Serialization Format

Every row is converted to a compact binary blob before being placed on a page:

```
Binary layout of one serialized row:

Offset   Size    Field           Notes
──────   ────    ────────────    ──────────────────────────────────────
0        8       expires_at      int64 Unix epoch; 0 = never expires
8        2       ncols           uint16 number of columns
10       2       col0_len        uint16 byte length of first value
12       N       col0_data       raw UTF-8 string for first value
12+N     2       col1_len
14+N     M       col1_data
...      ...     ...             repeated for every column

Example: INSERT INTO users VALUES (1, 'alice', 92.5)
expires_at=0  ncols=3
col0: len=1,  data='1'        (INT stored as string)
col1: len=5,  data='alice'    (TEXT/VARCHAR stored as-is)
col2: len=4,  data='92.5'     (DECIMAL stored as string)
```

All column values — including INT and DECIMAL — are stored as their string representations. This keeps serialization uniform: the same deserialization code handles every type. Type interpretation (parsing 92.5 as a double for a WHERE comparison) happens only at query evaluation time, not during storage. The cost is a small storage overhead: int64_t 1000000 takes 7 bytes as a string vs. 4 bytes

binary. For 10 million integers this wastes roughly 30 MB — negligible compared to disk I/O and network costs.

3.5 Row-Major vs. Column-Major — The Choice and Why

Row-major storage means all columns of a single row sit together in memory. Column-major means all values of one column across every row are stored together.

	Row-Major (Chosen)	Column-Major (Not Chosen)
INSERT speed	Single sequential append to one page	Must append to N separate arrays — N I/O ops
SELECT *	Whole row is one contiguous buffer	Row data scattered across N memory regions
Aggregations	Must skip other columns	Whole column is contiguous — ideal
INNER JOIN	Row projection is one memory region	Requires scatter-gather across N arrays
Cache line use	All columns of one row in same cache line	One column across rows — good for analytics

FlexQL uses row-major because the workload is OLTP-style (insert one row, look up full rows by primary key, scan and project full rows for SELECT). FlexQL does not support aggregation functions (SUM, COUNT, AVG, GROUP BY), so column-major offers no practical benefit for this system.

3.6 Schema Storage

When CREATE TABLE users (id INT PRIMARY KEY, name VARCHAR(64)) is executed, the server writes a schema file:

```
data/tables/users.schema:
  [sql_len: 4 bytes uint32][sql_text: sql_len bytes — original CREATE TABLE SQL]

  Example content: CREATE TABLE users(id INT PRIMARY KEY, name VARCHAR(64))
```

The schema file stores the original SQL verbatim. On server startup, all .schema files are read back and re-executed through the SQL parser. This rebuilds all Table structs (column names, types, primary key position, index structures) before any data pages are loaded. This design means schema recovery requires no special binary schema format: the SQL parser itself is the schema reader, and it is already thoroughly tested by normal operation.

3.7 In-Memory Table Representation

Inside the SQL engine, each table is represented by a Table struct. Understanding this struct is key to understanding the whole system:

```
struct Table {
    string name;
    vector<Column> columns;                            // ordered column definitions
    unordered_map<string, size_t> column_index;        // name → position, O(1)
    mutable shared_mutex mutex;                        // per-table RW lock
    int primary_key_col;                               // -1 if no PK declared
    unordered_map<string, uint64_t> primary_index;     // VARCHAR PK → encoded loc
    RobinHoodIndex pk_robin_index;                     // INT PK → encoded loc
    bool pk_is_int;                                    // which index to use
    uint64_t version;                                  // incremented on INSERT/DELETE
    unique_ptr<DiskManager> disk_mgr;                  // file I/O for this table
    unique_ptr<BufferPoolManager> buf_pool;             // 8192-frame RAM cache
    page_id_t last_page_id;                            // fast append — avoids scan
};
```

Each table has its own DiskManager and BufferPoolManager. This means tables are completely isolated — a large scan on orders cannot evict pages belonging to users. The version counter is the key mechanism for LRU cache invalidation. The column_index hash map gives O(1) name-to-position resolution instead of linear search.

3.8 Buffer Pool Manager

The buffer pool is the bridge between the SQL engine and the disk. It maintains 8192 fixed-size frames in RAM. Pages are loaded into frames on demand and evicted when frames are all occupied.

```
┌──────────────────────────────────────────────────────────────────────────┐
│  BufferPoolManager  (pool_size = 8192 frames)                            │
│                                                                          │
│  page_table: unordered_map<page_id → frame_idx>  O(1) lookup             │
│  lru_list:   [front=MRU ... back=LRU]                                    │
│  lru_pos:    unordered_map<frame_idx → list iterator>                    │
│  free_list:  available frame indices                                     │
│                                                                          │
│  Frames (8192 × 8 KB = 64 MB):                                          │
│  ┌──────────┬──────────┬──────────┬──────────┬──────────┐               │
│  │ Frame  0 │ Frame  1 │ Frame  2 │ Frame  3 │   ...    │               │
│  │ page=7   │ page=12  │ page=FREE│ page=99  │          │               │
│  │ pin=2    │ pin=0    │          │ pin=1    │          │               │
│  │ dirty=T  │ dirty=F  │          │ dirty=T  │          │               │
│  └──────────┴──────────┴──────────┴──────────┴──────────┘               │
└──────────────────────────────────────────────────────────────────────────┘
                                   │
                                   │  Frame needed?
                   ┌───────────────┴──────────────────┐
```

```
              Free list                          LRU eviction
              has entry?                   scan tail → pin_count == 0?
              → grab it                   → if dirty: pwrite() to disk
                                          → reuse frame
                                                  |
                                  ┌──────────────▼──────────────┐
                                  │  data/pages/<table>.db      │
                                  │  sequential 8KB blocks      │
                                  └─────────────────────────────┘
```

Pin / Unpin Protocol

Before accessing a page, the engine calls buf_pool->pin(page_id). This loads the page from disk into a frame if not already present, increments the pin_count, and returns a Frame*. The pin_count prevents eviction while the frame is in use — a running scan never has its pages stolen mid-execution. After finishing, unpin(page_id, dirty=true/false) decrements pin_count and marks the frame dirty if modified.

LRU Eviction

The pool tracks frame access order using a doubly-linked list (lru_list_) and a hash map (lru_pos_) for O(1) move-to-front. When eviction is needed, the pool walks the LRU tail for the first unpinned frame. If dirty, it is written to disk with pwrite() and then reused. The internal mutex is held only during the brief metadata update, not during the pwrite() disk I/O itself.

Per-Table Isolation

Each table has its own BufferPoolManager with its own 8192-frame pool. This guarantees that a large full scan on one table cannot evict hot pages belonging to another table. The tradeoff is memory: 10 tables × 64 MB = 640 MB of pool overhead regardless of actual data sizes. For the benchmark workload (one large table), this is optimal.

> **Why Not a Shared Pool?** A shared pool across all tables would be more memory-efficient but requires more complex eviction logic to prevent large scans from thrashing pages belonging to other tables. Per-table isolation keeps eviction simple and predictable.

3.9 Schema Persistence

When a CREATE TABLE statement is executed, the original SQL text is written to a .schema file in data/tables/<tablename>.schema. On server restart, DiskStore::load_schemas() reads all .schema files and re-executes the CREATE TABLE statements to rebuild the Table structs and column metadata in memory. This means the schema is always on disk and never lost across restarts.

```
// Schema file format: [uint32: sql_length][sql_bytes...]
// e.g. data/tables/student.schema contains the original:
// CREATE TABLE student(id INT PRIMARY KEY, name TEXT);
```

3.10 Write-Ahead Log (WAL)

To protect against data loss when the server crashes mid-operation, FlexQL uses a Write-Ahead Log. Every SQL statement that modifies data (CREATE TABLE, INSERT) is written to wal.log before (or shortly after) being applied to the in-memory structures.

```
Client Thread                  WAL Background Thread
─────────────                  ──────────────────────
INSERT INTO ... →  push SQL    ← queue
(returns immediately)              │
                                   ▼
                             batch drain loop
                             write to wal.log
                             fdatasync()

On crash recovery (server restart):
1. Read all .schema files → re-create table metadata
2. Scan data/pages/*.db   → reload row data + rebuild indexes
3. Replay wal.log entries → apply any uncommitted inserts
4. checkpoint_to_disk()   → flush everything, truncate WAL
```

Async WAL Worker

Writing to the WAL synchronously on every INSERT would reduce throughput significantly (one fdatasync per insert = catastrophic for a 10M row benchmark). Instead, the WAL uses a background worker thread. INSERT statements push their SQL text to a thread-safe queue and return immediately. The worker thread batches entries from the queue, writes them to wal.log, and calls fdatasync.

WAL File Format

```
// wal.log format: sequence of length-prefixed entries
// [uint32: sql_len][sql_bytes...][uint32: sql_len][sql_bytes...]...
```

Crash Recovery

On server restart, WAL::replay() reads all entries from wal.log and re-executes them through the SQL engine. After replay, checkpoint_to_disk() flushes all dirty pages and the WAL is truncated.

> **Tradeoff:** The async WAL worker means there is a brief window (milliseconds) where a power failure could lose a batch of inserts that were queued but not yet fsynced. This is the same tradeoff SQLite makes with PRAGMA synchronous=NORMAL, and it is acceptable for the throughput gains (~3-4x faster inserts).

4. Indexing

Without an index, answering SELECT * FROM users WHERE id = 5000000 on a 10-million-row table requires reading every single page and checking every row — over 80,000 pages. At the buffer pool's processing speed this takes over 14 seconds for one point query. With a primary key index, the same query completes in 0.023 milliseconds.

4.1 What Gets Indexed

FlexQL supports primary key indexing only. When a column is declared PRIMARY KEY, the engine maintains an index from that column's values to the physical storage location of each row. The location is encoded as a single uint64_t:

```
location = (page_id << 16) | slot_index

  page_id occupies bits 63..16  (48 bits — supports 2^48 pages = practically infinite)
  slot    occupies bits 15..0   (16 bits — up to 65,535 rows per page)

  Recovery:
    page_id = encoded_loc >> 16
    slot    = encoded_loc & 0xFFFF
```

Secondary indexes on non-PK columns are not implemented. Range queries on non-PK columns perform a full table scan via TableIterator. This is a conscious scope decision — implementing disk-backed B+ trees for secondary indexes would significantly increase code complexity.

4.2 Robin Hood Open-Addressing Hash Map (INT Primary Keys)

For INT PRIMARY KEY columns, FlexQL uses a custom RobinHoodIndex — a Robin Hood open-addressing hash map implemented as a single flat std::vector<Slot>. This is one of the most important performance decisions in the entire project.

```
  One flat std::vector<Slot>  — zero pointer chasing:

  struct Slot { int64_t key; uint64_t val; int dist; };  // dist=-1 means empty

  Index:  [ 0  ][ 1  ][ 2  ][ 3  ][ 4  ][ 5  ][ 6  ][ 7  ]
  Key:    [ 42 ][ 17 ][ -- ][ 99 ][ 56 ][ -- ][ 31 ][ -- ]
  Dist:   [  0 ][  1 ][ -1 ][  0 ][  2 ][ -1 ][  0 ][ -1 ]

  INSERT collision — Robin Hood 'steal from the rich' rule:
    incoming key probed D slots from ideal position
    existing key probed E slots from its ideal position
    if D > E → swap them (give the slot to the more-displaced key)
              → probe on with the displaced key
```

```
LOOKUP — early exit:
  pos = hash(key) & mask
  probe until: key matches (found) OR dist < expected_dist (not present)
  worst-case probe length is bounded — dramatically better than chaining

Hash function (Murmur3-style 64-bit finalizer):
  x ^= x >> 33
  x *= 0xff51afd7ed558ccdULL
  x ^= x >> 33
  x *= 0xc4ceb9fe1a85ec53ULL
  x ^= x >> 33
  → uniformly distributes sequential integers 1,2,3,4,... (no clustering)
```

Why Not std::unordered_map?

The standard library's hash map uses separate chaining. Each bucket is a linked list of heap-allocated nodes. Under load, lookups follow pointer chains through memory scattered across the heap. Each pointer dereference is a potential CPU cache miss (50–200 ns on modern hardware). For 5,000 sequential point queries on a 10M-row table, these cache misses dominate. Robin Hood's flat array keeps all slots within consecutive cache lines — 1–3 accesses per lookup regardless of table size.

Load Factor Management

The index rehashes when 75% full: (count + 1) * 4 >= capacity * 3. Before a bulk insert benchmark, reserve() is called with the expected row count to pre-allocate capacity and avoid rehash interruptions mid-batch.

Why Not a B-Tree?

A B-tree would support ordered range scans (WHERE id BETWEEN 1000 AND 2000). However, FlexQL's WHERE clause supports only single-condition filters, and the primary use case is equality lookup (WHERE id = X). Robin Hood hash maps deliver O(1) equality lookup with better CPU cache utilization than B-trees which are O(log N). If range queries on PK were needed, a B-tree or sorted array would be the correct addition.

Robin Hood Probing

Standard open-addressing (linear probing) suffers from primary clustering: when collisions happen, long chains of consecutive occupied slots form. Robin Hood probing fixes this by tracking the 'displacement distance' of each entry (how many slots it has been pushed from its ideal position). During insertion, if the new key has been displaced more than the existing occupant, they swap — the new key 'steals from the rich'. This keeps displacement variance very low, which means probe sequences are short.

Location Encoding

The index maps each int64 key to a uint64 location value that encodes both the page ID and slot number in a single 64-bit integer:

```
uint64_t loc = (static_cast<uint64_t>(page_id) << 16) | slot_number;
```

```
// Recovery: to look up a row by PK
page_id_t pid = loc >> 16;
uint16_t  slot = loc & 0xFFFF;
Frame* f = buf_pool->pin(pid);  // gets the page
// then read row bytes at the slot offset
```

4.3 Standard Hash Map (VARCHAR Primary Keys)

For string primary keys, std::unordered_map<string, uint64_t> is used as a fallback. The value is the same encoded location. String hashing is slower than integer hashing but correct. Most real workloads (including the benchmark) use INT PKs, so this path is rarely exercised.

4.4 Index Lookup Flow

When the query executor sees WHERE id = 42 and id is the primary key:

```
1.  Parse '42' as int64_t pk_val = 42
2.  pk_robin_index.lookup(42) → encoded_loc  OR  kEmpty
3.  If kEmpty: no row with this PK → return empty result immediately
4.  Decode: page_id = encoded_loc >> 16
            slot    = encoded_loc & 0xFFFF
5.  frame = buf_pool->pin(page_id)  → loads from disk if not cached
6.  Navigate to slot offset within frame->page
7.  deserialize_row() → PageRow
8.  row_alive(row, now_ts) check — skip if TTL expired
9.  evaluate_where(row, condition) — check any remaining WHERE condition
10. buf_pool->unpin(page_id, false)
11. Return result row

Steps 2-11 complete in ~23 microseconds including full TCP round-trip.
```

4.5 Index Rebuild on Server Startup

The in-memory index is not persisted separately to disk. On server restart, load_from_disk() uses a TableIterator to scan all pages in every table's .db file, deserializing each row and re-inserting its primary key into the index. For 10 million rows, this rebuild completes in a few seconds and is amortized across the startup sequence.

5. Caching Strategy

Executing SELECT * FROM bench_users WHERE score >= 50.0 on 10 million rows takes about 0.9 seconds. If 10 clients run the same query simultaneously, that is 9 seconds of redundant CPU work. An LRU query cache stores the result of a completed SELECT and serves future identical queries in microseconds.

5.1 LRU Cache Structure

```
QueryCache structure:

map_:     unordered_map<normalized_sql → list_iterator>   O(1) access
entries_: list< pair<sql, CacheEntry> >  (MRU head, LRU tail)

struct CacheEntry {
  QueryResult result;                      // rows + column names
  string      wire_bytes;                  // pre-serialized text protocol
  string      wire_bytes_bin;              // pre-serialized binary protocol
  unordered_map<string,uint64_t> versions; // table → version snapshot
  size_t      approx_bytes;                // memory footprint estimate
};

ON SELECT MISS:                           ON SELECT HIT:
  execute full scan                         versions match?
  build QueryResult + wire bytes              YES → splice to front
  cache.put(key, result, versions)                  → send wire_bytes directly
  if size > 2048 or mem > 512MB:              NO  → evict, re-execute
    evict LRU tail entry

INVALIDATION on INSERT:
  table.version++
  (no explicit eviction — stale check happens lazily on next HIT attempt)
```

Cache limits: maximum 2048 entries, maximum 512 MB total cache memory, single entries exceeding 256 MB are not cached (prevents one massive scan from poisoning the cache). The 2048-entry limit was increased from 512 to give more room for varied query patterns in multi-client workloads.

5.2 Cache Key — SQL Normalisation

Queries that differ only in whitespace or capitalisation must share one cache entry. Before keying, the SQL is normalised:

- All characters outside single-quoted literals are uppercased
- All whitespace runs collapse to a single space
- Leading / trailing whitespace is stripped

- Trailing semicolons are removed

All of these normalise to the same key: SELECT * FROM USERS:

```
"select * from users"
"SELECT  *  FROM users"
"SELECT * FROM USERS;"
"  SELECT * FROM users ;  "
```

Characters inside single-quoted string literals are never altered, so WHERE name = 'Alice' and WHERE name = 'alice' correctly produce different cache keys.

5.3 Cache Invalidation — Table Versioning

This is the most important part of the caching design. A cache entry must be invalidated whenever any table it references is modified. FlexQL does this through table version numbers.

Every Table struct has a monotonically increasing version counter. Every time an INSERT succeeds on a table, the counter increments. When a SELECT is cached, the cache entry stores a snapshot of the version numbers of all tables it touched. On a cache lookup, the stored versions are compared against the current versions. If any differ, the entry is immediately evicted and the query is re-executed.

Cache Hit Check: entry.versions == current_versions → valid, serve from cache

Cache Miss: versions differ (INSERT happened since caching) → evict, re-run

This gives strict read consistency: a SELECT always returns data that includes all inserts that completed before it.

5.4 Version-Based Invalidation

Every Table has a uint64_t version field starting at 1, incremented on every INSERT and DELETE. When a query result is cached, the current version of every touched table is recorded alongside the result. On a cache lookup, stored versions are compared against current versions. If any version has changed (an INSERT happened after caching), the entry is immediately evicted and the query re-executes.

```
CacheEntry.versions = { "users": 14, "orders": 7 }

Cache lookup:
  current = { users: 15, orders: 7 }   ← INSERT happened on users
  14 != 15  → EVICT, re-execute query

  current = { users: 14, orders: 7 }   ← nothing changed
  14 == 14, 7 == 7  → HIT, serve cached wire bytes
```

This gives strict consistency: a SELECT will never return stale data that excludes a completed INSERT.

5.5 Cases Where Caching Is Skipped

- Primary key point lookups (WHERE id = X): These use the Robin Hood index and complete in microseconds anyway. Caching them would pollute the LRU list with thousands of single-row results unlikely to be repeated. The engine detects this pattern and bypasses the cache entirely.
- Queries involving TTL rows: If any row scanned during execution had a non-zero expires_at, the result is time-sensitive. Caching it could cause expired rows to appear in future lookups. These queries set a has_ttl flag and are never stored in the cache.

5.6 Pre-Built Wire Bytes

A naive cache hit would still require re-serializing the QueryResult into the wire format before sending it. For 2 million rows, this serialization takes hundreds of milliseconds — comparable to re-executing the query.

To eliminate this overhead, the cache stores pre-built wire bytes alongside the result — one version for the text protocol and one for the binary protocol. On a cache hit, the server calls send_all(fd, wire_bytes.data(), wire_bytes.size()) and the entire response is sent in a single write. This is why cached queries show a 36% speedup in the benchmark: the remaining time is almost entirely kernel TCP send time for 2 million rows of data.

5.7 Buffer Pool Eviction — LRU vs. Alternatives

The buffer pool itself uses LRU eviction. Here is why LRU was chosen over the alternatives:

- LRU: Recently-accessed pages are very likely to be accessed again soon (temporal locality). A sequential scan accesses pages 0..N in order; after the scan, page 0 is the coldest. LRU naturally reflects this and keeps the hot working set in cache.
- CLOCK (approximate LRU): Cheaper to implement (no doubly-linked list), slightly worse hit rate. The implementation complexity saved is minimal — LRU was chosen for better accuracy.
- MRU (evict newest): Better for one-time sequential scans that will never repeat. FlexQL's workload is dominated by repeated scans and index lookups, so MRU would perform poorly.
- Buffer pool bypass (write-around): Large sequential scans that will never repeat could bypass the pool and write directly to disk. Not implemented to keep the buffer pool code simple and correct.

6. Expiration Timestamps — TTL

Many real workloads need data that automatically becomes invalid: session tokens, temporary locks, rate-limiting counters, leaderboard snapshots. Without native TTL support, the application must run periodic cleanup queries. FlexQL supports row-level expiration natively so this happens transparently at read time.

```
INSERT syntax → stored expires_at value:

INSERT INTO t VALUES (1,'alice') TTL 3600;
  → expires_at = now_unix() + 3600   (evaluated at INSERT time)

INSERT INTO t VALUES (2,'bob') EXPIRES 1767225600;
  → expires_at = 1767225600          (Unix epoch directly)

INSERT INTO t VALUES (3,'carol') EXPIRES '2026-12-31 23:59:59';
  → expires_at = mktime(parsed datetime)

INSERT INTO t VALUES (4,'dave');
  → expires_at = 0                   (never expires)

─── Lazy evaluation at read time ──────────────────────────────────
now_ts = now_unix()  ← computed once per query, passed to all paths

bool row_alive(const PageRow& row, int64_t now_ts) {
  return row.expires_at == 0 || row.expires_at > now_ts;
}

Called in: execute_select() full scan, index lookup path,
           JOIN build phase, JOIN probe phase.

TTL rows are NEVER cached (has_ttl flag prevents stale serving).
```

6.1 How Expiration is Stored

The expiration timestamp is stored as the very first 8 bytes of every serialized row (int64_t Unix epoch). A value of 0 means the row never expires. Every row always pays this 8-byte cost whether or not it uses TTL. The tradeoff is uniform serialization code with no conditional branches during row write.

6.2 Lazy Expiration — No Background Thread

FlexQL does not actively delete expired rows. Instead, they are filtered at read time. The row_alive() function is called for every row in every query path: full table scans, index lookups, JOIN build and probe

phases. now_unix() is called once at the start of each query and passed to all scan paths, so within a single query all rows are evaluated against the same timestamp — a consistent snapshot.

Lazy expiration means expired rows continue to occupy disk pages and buffer pool frames until the table is recreated or a DELETE FROM is issued. For workloads where rows expire frequently in large numbers, disk usage grows over time. A future VACUUM command could compact pages offline.

> **Tradeoff:** Lazy expiry adds 8 bytes per row and one integer comparison per scan. Background GC would reclaim disk space but requires write locks during compaction, causing latency spikes. For the current scope, lazy expiry is simpler, faster, and correct.

6.3 Cache Interaction

Results from queries that touch any row with a non-zero expires_at are never stored in the LRU cache. This is enforced by the has_ttl flag set during scanning. If a cached result were served after some rows had expired, the client would receive stale (artificially large) result sets.

6.4 Supported Expiration Syntax

```
-- TTL: expires N seconds from now
INSERT INTO session VALUES (1, 'token_abc') TTL 3600;

-- EXPIRES with Unix timestamp:
INSERT INTO session VALUES (2, 'token_xyz') EXPIRES 1893456000;

-- EXPIRES with datetime string:
INSERT INTO session VALUES (3, 'tok') EXPIRES '2030-01-01 00:00:00';

-- No TTL: row lives forever
INSERT INTO session VALUES (4, 'forever');
```

7. Multithreading and Concurrency

A single-threaded server processes one query at a time. While one client waits for a large full scan to complete, all other clients are blocked. FlexQL is designed so that multiple concurrent reads proceed in genuine parallel — on different CPU cores, with zero contention between them. The entire concurrency design is built around three principles: avoid global locks, separate read and write access, and never hold a lock during disk I/O.

7.1 Thread Pool

Instead of spawning a new thread for every client connection (which has high overhead at scale), the server uses a pre-allocated thread pool of 2 × hardware_concurrency worker threads. Each accepted client connection is submitted as a task to the pool. Workers pick up tasks from a shared queue protected by a mutex and condition variable.

```
   Client A ──┐
   Client B ──┤                  ┌──────────────────────────┐
   Client C ──┼──→  accept() ──→│  Thread Pool Task Queue   │
   Client D ──┤                  │  [task_A, task_C, task_B ...] │
   Client E ──┘                  └──────────────────────────┘
                                            │
                                            │
              ┌──────────────────────────────▼──────────────────┐
              │  Worker threads (2 × hardware_concurrency)      │
              │  Thread-1    Thread-2    Thread-3  ...          │
              │     │            │           │                  │
              │  handle_client() handle_client() ...            │
              └──────────────────────────────────────────────────┘
                          │
              Per-table locking model:
              SELECT → shared_lock(table.mutex)   ← multiple readers OK
              INSERT → unique_lock(table.mutex)   ← exclusive write
              CREATE → unique_lock(db_mutex_)     ← global for schema changes
```

When a client connects, the server does not spawn a new OS thread per connection. Thread creation costs 100–300 µs and OS thread stacks consume memory. Instead, FlexQL uses a fixed-size thread pool with 2 × hardware_concurrency threads, all created once at startup.

```
const size_t hw = std::thread::hardware_concurrency();
ThreadPool pool(hw > 0 ? hw * 2 : 16);

// On each client connect:
pool.submit([client_fd, &engine]() {
    handle_client(client_fd, &engine);  // handles ALL queries on this connection
});
```

The factor of 2 accounts for threads blocking on network I/O (waiting for the next query from the client). Having more threads than CPU cores keeps all cores busy while some threads wait for data. The pool

uses a std::queue<function<void()>> protected by a mutex and condition_variable. Workers sleep until a task arrives.

7.2 Two-Level Reader-Writer Locking

A single global mutex protecting all tables would be simple but terrible for performance. Two concurrent SELECT queries on different tables would block each other unnecessarily. FlexQL uses a two-level locking hierarchy:

Level 1 — Global Database Mutex (db_mutex_)

This is a shared_mutex protecting the tables_ hash map itself. It is used exclusively when the structure of the map changes (CREATE TABLE, DROP). SELECT and INSERT operations on existing tables acquire only a shared lock on db_mutex_, allowing multiple operations to proceed concurrently at the global level.

Level 2 — Per-Table Mutex (table.mutex)

Every Table struct has its own shared_mutex. SELECT queries take a shared_lock — multiple threads can read the same table simultaneously with no blocking. INSERT queries take a unique_lock — exclusive write access to that specific table. Two threads inserting into different tables do not block each other at all.

Operation	Lock Taken	Blocked By
SELECT	shared_lock(table.mutex)	Only blocked by concurrent INSERT on same table
INSERT	unique_lock(table.mutex)	Blocked by any concurrent SELECT or INSERT on same table
CREATE TABLE	unique_lock(db_mutex_)	Blocked by any other CREATE TABLE
SELECT on different tables	Independent locks	Never blocks each other

INNER JOIN Deadlock Prevention

INNER JOIN accesses two tables. If thread A locks table users then orders, and thread B locks orders then users, they deadlock. FlexQL avoids this by always acquiring the two table locks in alphabetical order of table name. This guarantees a consistent lock acquisition order and makes deadlock impossible

This is the most important concurrency design decision in the system. FlexQL uses two nested std::shared_mutex locks to achieve fine-grained parallelism:

```
db_mutex_ (shared_mutex)  — global, protects tables_ map structure
┌──────────────────────────────────────────────────────────────┐
│  shared_lock(db_mutex_)   ← SELECT, INSERT (table lookup)    │
│  unique_lock(db_mutex_)   ← CREATE TABLE only                │
└──────────────────────────────────────────────────────────────┘
                              │
```

```
                                ▼
  table.mutex (shared_mutex per Table) — per-table locking
  ┌──────────────────────────────────────────────────────────────┐
  │  shared_lock(table.mutex)  ← SELECT (many readers OK)        │
  │  unique_lock(table.mutex)  ← INSERT, DELETE (exclusive)      │
  └──────────────────────────────────────────────────────────────┘

  INNER JOIN — two tables — deadlock prevention:
    always acquire in ALPHABETICAL ORDER by table name
    shared_lock ta(name_A <= name_B ? mutexA : mutexB);
    shared_lock tb(name_A <= name_B ? mutexB : mutexA);
    → consistent order across all threads → no circular waits

  BufferPool:   internal mutex — held only for frame table update
  QueryCache:   internal mutex — held only for map lookup/splice
  WAL:          internal mutex — held only for queue push/pop
    → none of these hold locks during actual disk I/O
```

Scenario	Result
10 clients SELECT from users simultaneously	All 10 proceed in parallel — zero contention
INSERT to users + SELECT from orders concurrently	Both proceed simultaneously — different tables
INSERT to users + SELECT from users concurrently	SELECT waits for INSERT to finish on users
2 clients both INSERT into users	Second INSERT waits for first to complete
2 clients CREATE TABLE (different names)	Second waits — db_mutex_ exclusive lock

7.3 Deadlock Prevention in INNER JOIN

INNER JOIN must lock two tables simultaneously. If thread A locks table users then orders, while thread B locks orders then users, they deadlock. FlexQL prevents this by always acquiring table locks in alphabetical order by table name. Since all threads always acquire locks in the same order, circular waits cannot form by the Coffman conditions.

```
// Always lock in alphabetical name order:
shared_lock<shared_mutex> ta(
    base.name <= right_ptr->name ? base.mutex : right_ptr->mutex);
shared_lock<shared_mutex> tb(
    base.name <= right_ptr->name ? right_ptr->mutex : base.mutex);
```

7.4 Buffer Pool, Cache, and WAL Thread Safety

Each subsystem manages its own thread safety independently:

- BufferPoolManager: internal std::mutex held only during frame table update and LRU list manipulation — NOT during pread/pwrite disk I/O. Two threads can perform disk I/O for different pages simultaneously.
- QueryCache: internal std::mutex held only during map lookup and LRU list splice. Not held during query execution or result serialization.
- WAL background thread: communicates via std::queue + std::mutex + std::condition_variable. Insert threads push to the queue and return immediately. The WAL worker drains and fsyncs without holding any table lock.

7.5 CPU Frequency Warm-Up

Modern CPUs idle at 2.5 GHz or lower and boost to 3.5–5.0 GHz under sustained load. Without a warm-up, the first benchmark run measures at base clock and appears 30–60% slower than subsequent runs. The server runs a 300 ms computation-heavy busy-loop immediately after binding to the port, before calling accept(), to force the CPU into turbo frequency before the first query arrives.

```
using clk = std::chrono::steady_clock;
auto end = clk::now() + std::chrono::milliseconds(300);
volatile uint64_t acc = 0xdeadbeefcafe1234ULL;
while (clk::now() < end) {
    acc ^= (acc << 13) ^ (acc >> 7) ^ (acc << 17);
}
(void)acc;  // suppress unused-variable warning
```

8. SQL Parsing and Query Execution

All SQL parsing and execution happens inside SqlEngine (sql_engine.cpp, ~1900 lines). The parser is hand-written — no parser generator (Bison, ANTLR, yacc) is used. The supported SQL subset is small and well-defined, and a hand-written parser gives precise control over error messages, performance, and normalization behavior.

8.1 How the Parser Works

The parser works in a single pass:

1. Detect statement type from the first non-space keyword (CREATE, INSERT, SELECT, DELETE).
2. Scan for clause boundary keywords (FROM, WHERE, INNER JOIN, ON, ORDER BY, VALUES) using find_keyword(), which correctly ignores keywords inside string literals.
3. Extract substrings for each clause and process them independently.
4. Split comma-separated lists with split_csv(), which respects nested parentheses and string literals.
5. Normalize all identifiers to lowercase immediately for case-insensitive matching.

All string literals are handled with proper quote escaping — single quotes can be doubled ('it''s alice') and double quotes are also supported.

8.2 Supported SQL Statements

Statement	Notes
CREATE TABLE t (col type [PK] [NOT NULL], ...)	Standard DDL — creates table and schema file
CREATE TABLE IF NOT EXISTS t (...)	Silently resets table if it already exists
PRIMARY KEY(col) as table constraint	Supported separately from inline PK declaration
INSERT INTO t VALUES (v1, v2, ...)	Single row
INSERT INTO t VALUES (...), (...), (...)	Multi-row batch — strongly recommended
... TTL <seconds>	Row expires N seconds from INSERT time
... EXPIRES <unix_epoch>	Row expires at exact Unix timestamp
... EXPIRES '<datetime>'	Row expires at YYYY-MM-DD HH:MM:SS
SELECT * FROM t	Full scan, all columns
SELECT col1, col2 FROM t	Full scan, projected columns
SELECT ... WHERE col op val	Filtered scan — one condition only
SELECT ... INNER JOIN ... ON t.c = u.c	Hash join on equality condition

Statement	Notes
SELECT ... INNER JOIN ... ON t.c >= u.c	Range join — probe-phase nested loop
SELECT ... ORDER BY col [ASC|DESC]	Stable sort applied to result rows
DELETE FROM t	Clears all rows, resets index and buffer pool

Column types: INT / INTEGER, DECIMAL, VARCHAR(n) / VARCHAR / TEXT, DATETIME. WHERE operators: =, !=, <, <=, >, >=.

8.3 Type Validation at INSERT Time

Each value in an INSERT is validated against its column's declared type before anything is written to disk:

- INT: Must parse as int64_t via std::from_chars. Scientific notation is rejected.
- DECIMAL: Must parse as double. std::from_chars is tried first; strtod is the fallback.
- DATETIME: Must match YYYY-MM-DD HH:MM:SS or YYYY-MM-DDTHH:MM:SS, converted to Unix epoch via mktime.
- VARCHAR(n): String must be at most n bytes if a limit was declared.
- NULL is rejected for columns declared NOT NULL or PRIMARY KEY.

If validation fails on any row in a batch, the entire batch is rejected. No rows are written. This provides all-or-nothing semantics for batch inserts — either all 16,384 rows succeed or none do.

8.4 SELECT Execution Strategies

The query executor chooses between three strategies:

Strategy 1 — Primary Key Index Lookup (WHERE pk = value)

O(1) Robin Hood hash map lookup. Fetches exactly one page from the buffer pool. Result is at most one row. Cache is bypassed for this path. This is the fast path for the point query benchmark (0.023 ms average).

Strategy 2 — Full Table Scan with Filter

TableIterator walks every page from 0 to num_pages - 1. For each page, it pins the frame, deserializes all rows, checks TTL, evaluates the WHERE condition, and emits matching rows. Page is unpinned after all rows on it are processed.

Strategy 3 — Full Table Scan, No Filter

Same as Strategy 2 but condition evaluation is skipped. Output vector is pre-reserved to avoid reallocations.

After execution, if ORDER BY is present, std::stable_sort is applied to out.rows using a typed comparator — numeric sort (int64_t) for INT/DECIMAL, string comparison for VARCHAR/TEXT.

8.5 INNER JOIN — Hash Join

```
INNER JOIN users ON users.id = orders.user_id

─── Nested Loop (NOT used) ──────────────────────────────────
for each row in users:         O(N)
  for each row in orders:      O(M)
    if users.id == orders.user_id: emit     total: O(N × M)
At N=M=5M: 25 trillion comparisons — infeasible.

─── Hash Join (USED) ────────────────────────────────────────
BUILD PHASE (scan smaller table):
  join_hash[row.join_col].push_back(row)    O(N)

PROBE PHASE (scan larger table):
  for each probe_row in larger_table:       O(M)
    matches = join_hash[probe_row.join_col] O(1) avg
    for each match:
      if WHERE filter passes: emit combined row

Total: O(N + M)  — linear in both table sizes.

For range joins (ON a.score >= b.threshold):
  hash map is still built, but probe phase evaluates range condition
  against all hash map entries → falls back to O(N × K) where K
  is average bucket size (acceptable for small K).
```

8.6 DELETE Execution

DELETE FROM table drops all rows in a table and resets its storage:

6. Primary key index is cleared (pk_robin_index = RobinHoodIndex(1024), primary_index.clear())
7. buf_pool->flush_all() writes all dirty pages to disk
8. The .db file is deleted from disk (std::filesystem::remove)
9. A new empty DiskManager and BufferPoolManager are created for the table
10. last_page_id is reset to INVALID_PAGE_ID
11. table.version is incremented, invalidating all LRU cache entries for this table

The table schema is preserved — CREATE TABLE does not need to be re-run. The next INSERT after a DELETE starts a fresh empty .db file.

9. Network Protocol and Client API

9.1 Wire Protocol

The protocol is text-based and line-oriented, making it easy to debug with standard tools (nc, Wireshark, tcpdump). An optional binary mode exists for performance-sensitive clients. Binary mode eliminates all tab-escaping overhead and is faster to serialize and deserialize for large result sets.

```
  ─── Client → Server ──────────────────────────────────────────────────
  Text   mode:   Q  <sql_byte_count>\n<sql_bytes>
  Binary mode:   QB <sql_byte_count>\n<sql_bytes>

  ─── Server → Client (text success) ──────────────────────────────────
  OK <column_count>\n
  COL\t<col1>\t<col2>\t...\n
  ROW\t<val1>\t<val2>\t...\n
  ROW\t<val1>\t<val2>\t...\n
  END\n

  ─── Server → Client (binary success, QB mode) ───────────────────────
  [0x01]                        ← OK frame type (1 byte)
  [column_count: uint32 BE]
  [row_count:    uint32 BE]
  for each column:  [name_len: uint16 BE][name_data]
  for each row:
    for each column:  [val_len: uint32 BE][val_data]

  ─── Server → Client (text error) ────────────────────────────────────
  ERR\t<escaped_error_message>\n

  ─── Server → Client (binary error) ──────────────────────────────────
  [0x02]                        ← ERROR frame type (1 byte)
  [msg_len: uint32 BE][msg_data]

  Field escaping (text mode):  \t→\\t   \n→\\n   \\→\\\\
  Binary mode eliminates all escaping overhead.
#define FLEXQL_OK             0   // success
#define FLEXQL_ERROR          1   // general error
#define FLEXQL_NOMEM          2   // memory allocation failed
#define FLEXQL_NETWORK_ERROR  3   // TCP connection failure
#define FLEXQL_PROTOCOL_ERROR 4   // malformed server response
#define FLEXQL_SQL_ERROR      5   // invalid SQL

typedef struct FlexQL FlexQL;  // opaque handle

int  flexql_open (const char *host, int port, FlexQL **db);
int  flexql_close(FlexQL *db);
```

```
int  flexql_exec (FlexQL *db, const char *sql,
                  int (*callback)(void*,int,char**,char**),
                  void *arg, char **errmsg);
void flexql_free (void *ptr);
```

Receive Buffering

The client maintains a 65,536-byte receive buffer in thread-local storage. recv_line() reads from this buffer rather than calling recv() per character. One recv() call refills the buffer when exhausted. The buffer automatically doubles in size if a single line exceeds 65,536 bytes (e.g., very wide rows).

Send Batching

The server does not call send() once per row. It accumulates rows into a 256 KB string buffer and flushes when full or at the END marker. For a 2-million-row result this reduces send() syscalls from 2 million to roughly 30 — a 60,000x reduction in system call overhead.

9.2 flexql_open

Resolves the hostname using getaddrinfo (supports both IPv4 and IPv6), opens a TCP socket, connects, and sets TCP_NODELAY. The FlexQL struct is heap-allocated and returned via the db out-parameter. Returns FLEXQL_OK on success.

9.3 flexql_exec

Sends the SQL as a length-prefixed request over the socket (QB header for binary mode). Reads the response: binary responses are parsed directly into callback invocations without building intermediate string arrays where possible. The callback is invoked once per result row with:

- data: the void* arg pointer passed by the caller
- columnCount: number of columns in the result
- values: array of char* pointing to column values (NULL for SQL NULL)
- columnNames: array of char* pointing to column names (uppercase in REPL output)

If the callback returns 1, query execution is aborted (no more rows are processed). This is useful for LIMIT-style early termination.

Error messages are stored in a heap-allocated string and returned via the errmsg out-parameter. Callers must free this with flexql_free() to avoid memory leaks.

9.4 TCP Socket Tuning

Socket Option	Value	Effect
TCP_NODELAY	enabled	Disables Nagle's algorithm — eliminates ~40ms delay per query on loopback
SO_RCVBUF	16 MB	Large receive buffer — handles big INSERT batches without stalling
SO_SNDBUF	16 MB	Large send buffer — handles large SELECT results without stalling
SO_REUSEADDR	enabled	Allows instant server restart after shutdown (no TIME_WAIT wait)
SO_REUSEPORT	enabled	Allows multiple sockets on the same port if needed

9.5 C Client API — Reference

```
#define FLEXQL_OK             0   // success
#define FLEXQL_ERROR          1   // general error (invalid arguments, etc.)
#define FLEXQL_NOMEM          2   // memory allocation failed
#define FLEXQL_NETWORK_ERROR  3   // TCP connect/send/recv failed
#define FLEXQL_PROTOCOL_ERROR 4   // server sent unexpected bytes
#define FLEXQL_SQL_ERROR      5   // SQL syntax or semantic error

typedef struct FlexQL FlexQL;  // opaque — internal struct hidden from callers

// Open a TCP connection to a FlexQL server
int flexql_open(const char* host, int port, FlexQL** db);

// Execute a SQL statement; callback invoked once per result row
// Return 1 from callback to abort early, 0 to continue
// errmsg is malloc'd — caller must call flexql_free(errmsg) if non-NULL
int flexql_exec(FlexQL* db,
                const char* sql,
                int (*callback)(void* data, int ncols,
                                char** values, char** colnames),
                void* arg,
                char** errmsg);

// Close the connection and free all resources
int flexql_close(FlexQL* db);

// Free a string allocated by the library (e.g., errmsg)
void flexql_free(void* ptr);
```

The FlexQL handle is opaque — its definition (struct FlexQL { int fd; }) is hidden in the implementation file so users cannot access the socket descriptor. flexql_free() wraps std::free() and must be called on any non-NULL errmsg returned by flexql_exec().

9.6 Complete Usage Example

```
#include "flexql.h"
#include <stdio.h>

// Callback: invoked once per result row
int print_row(void *data, int ncols, char **vals, char **cols) {
    for (int i = 0; i < ncols; i++)
        printf("%s = %s\n", cols[i], vals[i] ? vals[i] : "NULL");
    printf("\n");
    return 0;  // return 1 to abort early
}

int main() {
    FlexQL *db = NULL;
    char *err  = NULL;

    // 1. Connect
    if (flexql_open("127.0.0.1", 9000, &db) != FLEXQL_OK)
        return 1;

    // 2. Create table
    flexql_exec(db, "CREATE TABLE users (id INT PRIMARY KEY,"
                    " name VARCHAR(64), score DECIMAL);",
                NULL, NULL, &err);

    // 3. Batch insert
    flexql_exec(db, "INSERT INTO users VALUES"
                    " (1,'alice',92.5),(2,'bob',88.0),(3,'carol',95.0);",
                NULL, NULL, &err);

    // 4. Insert with TTL
    flexql_exec(db, "INSERT INTO users VALUES (4,'dave',77.5) TTL 3600;",
                NULL, NULL, &err);

    // 5. Query with WHERE
    flexql_exec(db, "SELECT * FROM users WHERE score >= 90;",
                print_row, NULL, &err);

    // 6. Cleanup
    if (err) { fprintf(stderr, "Error: %s\n", err); flexql_free(err); }
    flexql_close(db);
    return 0;
}
```

10. Write-Ahead Log and Crash Recovery

The buffer pool writes dirty pages to disk during LRU eviction or at explicit checkpoint. Between evictions, recently-inserted rows may exist only in RAM. A kill -9 or power failure at this moment would lose those rows permanently. The Write-Ahead Log (WAL) solves this by ensuring every committed statement is durably recorded before the server's RAM is lost.

```
Query threads (concurrent)                WAL background worker thread
──────────────────────────                ────────────────────────────

INSERT → validate → write page
WAL::instance().log(sql)  ──push──▶   condition_variable.notify_one()
return FLEXQL_OK immediately                  │
                                              ▼ wakes, drains entire queue
(server is free for next query)        build batch string buffer
                                       file_.write(batch)
                                       fdatasync(fd_)  ← durable
                                       sleep again

CRASH RECOVERY SEQUENCE (server restart):
─────────────────────────────────────────
1. Read data/tables/*.schema → re-execute CREATE TABLE SQL
   → rebuilds all Table structs, column defs, index structures
2. load_from_disk(): scan data/pages/<table>.db via TableIterator
   → deserializes every row, rebuilds primary key indexes
3. WAL::replay("data/wal/wal.log")
   → reads [len][sql] records, re-executes any INSERT not yet in pages
4. checkpoint_to_disk(): flush all dirty frames, fdatasync all .db files
5. Truncate wal.log (clean slate) → open new WAL for appending
6. Enter accept() loop — server ready
```

10.1 WAL File Format

```
data/wal/wal.log:
  [sql_len: 4 bytes uint32][sql_text: sql_len bytes]
  [sql_len: 4 bytes uint32][sql_text: sql_len bytes]
  ...

  Each record is the raw SQL string of one committed statement.
  Replay is linear from the beginning of the file.
  The file is truncated to zero after a successful checkpoint.
```

10.2 Async WAL Writer

Calling fdatasync() on every INSERT would cap throughput at roughly the storage device's fsync IOPS (typically 1,000–10,000 per second on SSDs). To avoid this, WAL writes happen on a dedicated background thread. Because records are batched, even 100,000 concurrent INSERTs may result in very

few actual fdatasync calls — the per-fsync amortized cost approaches zero. A 4 MB internal write buffer is used to further reduce kernel write calls.

10.3 Clean Shutdown

On SIGINT or SIGTERM, a std::atomic<bool> g_shutdown flag causes the accept() loop to exit. Before main() returns, checkpoint_to_disk() flushes every dirty buffer pool page and fdatasyncs every table's .db file. After a clean shutdown, the WAL is unnecessary because all data is durably in the .db files. The next startup skips WAL replay and loads directly from pages.

> **Durability Guarantee:** Process-level crashes (SIGKILL, segfaults) are always safe because pwrite() writes to the OS page cache, which survives process termination. Hardware power loss is handled by the async WAL, with a brief window of potential data loss equal to the WAL worker's batch interval (typically milliseconds).

11. Design Tradeoffs

Every design choice in FlexQL was a tradeoff. This section documents them honestly — what was gained, what was given up, and why.

11.1 Async WAL vs. Synchronous Durability

Chosen: WAL writes are batched and fdatasync'd by a background thread, not inline with INSERT.

- Gained: INSERT throughput is not bottlenecked by fsync latency (1–5 ms on SSDs). Enables 700,000–985,000 rows/sec.
- Given up: If the server is killed between sending the INSERT response and the WAL thread's fdatasync, that INSERT could be lost despite the client believing it succeeded. This is the PRAGMA synchronous = NORMAL tradeoff from SQLite.
- Why: For the benchmark workload, throughput is the primary metric. Process-level crashes (not hardware failures) are already handled by the OS page cache surviving the process.

11.2 Lazy Row Expiration vs. Active GC

- Chosen: Expired rows are filtered at read time and never physically removed.
- Gained: No background cleanup thread, no write locks for compaction, zero CPU overhead on tables with few expired rows. The row_alive() check is one 64-bit integer comparison per row.
- Given up: Expired rows consume disk space indefinitely. High-churn TTL tables grow without a reclaim mechanism.
- Why: Physical deletion from the middle of a page requires compaction — shifting rows, updating indexes, rewriting pages. This complexity is not justified for the current scope.

11.3 Batch INSERT vs. Single-Row Inserts

- Chosen: The benchmark sends 16,384 rows per SQL statement.
- Gained: Each batch is one TCP round-trip, one SQL parse, one lock acquisition, one WAL entry for 16,384 rows. Per-row overhead drops from ~1 μs to ~0.001 μs for these fixed costs.
- Given up: If a batch fails (type error in row 5,000), the entire batch is rejected. Applications must handle retry logic.
- Why: Network round-trip time is the dominant bottleneck for single-row inserts. Batching is the single largest throughput optimization in the system (~40x improvement over single-row inserts).

11.4 Per-Table Buffer Pools vs. Shared Pool

- Chosen: Each table has its own BufferPoolManager with its own 8192-frame pool.
- Gained: Full table isolation. A large scan on orders cannot evict hot pages for users. Table-level DELETE can reset its pool without affecting others.
- Given up: Memory scales with table count. 10 tables × 64 MB = 640 MB pool overhead regardless of actual data sizes.
- Why: Isolation simplicity outweighs memory overhead for the primary workload (small number of large tables).

11.5 Robin Hood Hash vs. B-Tree

- Chosen: Primary key lookups use a Robin Hood flat-array hash map.
- Gained: O(1) equality lookup with 1–3 cache line accesses per lookup. Significantly faster than B-tree O(log N) for point queries.
- Given up: Hash maps cannot do ordered range scans. WHERE id BETWEEN 1000 AND 2000 degrades to a full table scan. A B-tree would answer this in O(log N + K).
- Why: The benchmark and test workloads use WHERE id = X exclusively. Robin Hood wins decisively for equality-heavy workloads.

11.6 String Representation for All Values

- Chosen: All column values — including INT and DECIMAL — are stored as their string representation.
- Gained: Uniform serialization format. No type metadata needed in page data. Same deserialization code for every type.
- Given up: Storage overhead — int64_t 1000000 takes 7 bytes as string vs. 4 bytes binary. For 10M integers this wastes ~30 MB.
- Why: Implementation simplicity. The storage overhead is negligible compared to disk I/O and network costs.

12. Compilation and Execution Instructions

12.1 Prerequisites

Compiler	g++ version 7+ or clang++ 7+ with C++17 support
Build Tool	GNU make (or CMake 3.16+)
OS	Linux — POSIX APIs (pread, pwrite, getaddrinfo, pthread)
Libraries	None external — standard C++17 and POSIX only
Disk	~100 GB free for 100M row stress test

12.2 Build

```
git clone https://github.com/Ludirm02/FlexQL.git
cd FlexQL

# Full clean build with all optimizations
make clean && make -j$(nproc)

# Build flags used:
# -O3 -DNDEBUG -flto -march=native -funroll-loops
# -fomit-frame-pointer -ffast-math -ftree-vectorize

# Alternative — CMake:
mkdir build_cmake && cd build_cmake
cmake .. -DCMAKE_BUILD_TYPE=Release && make -j$(nproc)
```

Binaries are placed in build/ with symlinks in bin/:

Binary	Purpose
bin/flexql_server	The database server daemon
bin/flexql-client	Interactive REPL terminal
bin/flexql_smoke_test	Basic CREATE / INSERT / JOIN / SELECT correctness check
bin/flexql_benchmark	21 unit tests + performance benchmarks

12.3 Starting the Server

```
# Create required data directories
mkdir -p data/wal data/pages data/tables
```

```
# Start server on default port 9000 (background)
./bin/flexql_server &

# OR on a custom port:
./bin/flexql_server 8080 &

# Wait for startup (server prints 'Disk storage loaded.'9
# and 'FlexQL server listening on port 9000')
sleep 2
```

12.4 Connecting with the Interactive REPL

```
# Connect to server
./bin/flexql-client 127.0.0.1 9000

# Expected output:
Connected to FlexQL server
Enter SQL statements ending with ';'. Type '.exit' to quit.
flexql>

# Example session:
flexql> CREATE TABLE student(id INT PRIMARY KEY, name TEXT);
OK
flexql> INSERT INTO student VALUES (1,'Alice'),(2,'Bob');
OK
flexql> SELECT * FROM student;
ID = 1
NAME = Alice

ID = 2
NAME = Bob

flexql> SELECT * FROM student WHERE id = 1;
ID = 1
NAME = Alice

flexql> .exit
Connection closed
```

12.5 Run the Smoke Test

```
./build/flexql_smoke_test 127.0.0.1 9000
# Expected: Smoke test passed

# Verifies: CREATE TABLE, INSERT, TTL INSERT,
#           INNER JOIN with WHERE, result set correctness
```

12.6 Run the 21 Unit Tests

```
./bin/flexql_benchmark --unit-test
# Expected: Unit Test Summary: 21/21 passed, 0 failed.

# Tests cover: CREATE TABLE, INSERT (single + multi-row),
# SELECT *, single-row lookup, WHERE inequality, empty results,
# INNER JOIN with no matches, invalid column name (error case),
# missing table name (error case), and more.
```

12.7 Run Performance Benchmarks

```
# ALWAYS wipe data and restart server for a clean benchmark
killall -9 flexql_server 2>/dev/null
rm -rf data/tables/* data/wal/* data/pages/*
./bin/flexql_server > server.log 2>&1 &
sleep 2

# 1 Million rows
./bin/flexql_benchmark 1000000

# 10 Million rows (primary benchmark)
./bin/flexql_benchmark 10000000

# 100 Million rows (out-of-core stress test — ~145 seconds)
./bin/flexql_benchmark 100000000

# Via script (auto-restart, saves results to docs/):
./scripts/run_benchmark.sh 9000 10000000
```

Expected output format:

```
rows_inserted=10000000
insert_total_seconds=10.15
insert_rows_per_second=985221
point_queries=5000
point_query_total_seconds=0.124914
point_query_avg_ms=0.0249828
full_scan_rows_returned=5000000
full_scan_seconds=1.2396
cached_query_rows_first=2000000
cached_query_rows_second=2000000
cached_query_first_seconds=0.383657
cached_query_second_seconds=0.339793
```

12.8 Testing Crash Recovery (Persistence)

```
# Step 1: Fresh start
killall -9 flexql_server 2>/dev/null
rm -rf data/tables/* data/wal/* data/pages/*
./bin/flexql_server > server.log 2>&1 &
sleep 2

# Step 2: Insert data (creates TEST_USERS table with 4 rows)
./bin/flexql_benchmark --unit-test

# Step 3: Start large background insertion
./bin/flexql_benchmark 1000000 > /dev/null 2>&1 &
sleep 1

# Step 4: Brutally kill the server mid-insertion
killall -9 flexql_server

# Step 5: Verify WAL captured unflushed data
ls -lh data/wal/wal.log   # Should be non-empty

# Step 6: Restart — WAL is replayed automatically on startup
./bin/flexql_server > server_recovery.log 2>&1 &
sleep 3

# Step 7: Build and run crash recovery validator
g++ -std=c++17 -Wall tests/crash_test.cpp src/client/flexql_client.cpp \
    src/network/protocol.cpp -Iinclude -Isrc -Isrc/network -o bin/crash_test
./bin/crash_test

# Expected output:
[PASS] TEST_USERS survived crash with 4 rows
[PASS] BIG_USERS survived crash, found 1 row(s) for ID=1
```

12.9 Run the Master Automated Script

```
./scripts/run_all_tests.sh

# Automatically:
# 1. Kills any running server, wipes all data directories
# 2. Starts fresh server daemon
# 3. Runs all 21/21 unit tests
# 4. Runs 10M row insert benchmark
# 5. Simulates kill -9 crash mid-insertion
# 6. Restarts server, verifies WAL replay recovered data
# 7. Cleans up processes
```

12.10 Stop the Server

```
# Graceful shutdown (triggers checkpoint_to_disk + fdatasync)
kill $(pgrep flexql_server)

# Force stop
killall -9 flexql_server
```

13. Performance Results

13.1 Test Environment

Hardware	AMD Ryzen 5 5600H, ~7 GB RAM available, NVMe SSD
Compiler	g++ with -O3 -march=native -flto -ffast-math -funroll-loops
Network	Loopback (127.0.0.1) — no real network latency
Schema	id INT PK, name VARCHAR(64), email VARCHAR(64), balance DECIMAL, expires_at DECIMAL
Batch size	16,384 rows per INSERT statement
CPU warm-up	300 ms busy-loop on server startup

13.2 Insert Throughput

Dataset	Elapsed	Throughput	Notes
1,000,000 rows	~2.5 sec	~390,625 rows/sec	Cold start, buffer pool warming up
10,000,000 rows	~10.2 sec	~985,000 rows/sec	Primary benchmark — peak throughput
100,000,000 rows	~145.5 sec	~687,000 rows/sec	Out-of-core — buffer pool eviction active, no OOM

The increase from 1M to 10M reflects CPU turbo-boost warming up and batch amortization becoming more efficient at scale. The slight drop at 100M is due to buffer pool evictions hitting disk — pages that no longer fit in the 64 MB pool are written to the .db file, adding I/O latency. The system did not OOM at 100M rows, confirming the buffer pool eviction design is correct.

13.3 Query Performance

Query Type	Result	Details
Point query (WHERE pk=x)	0.023 ms avg	5000 queries, includes full TCP round-trip + index lookup
Full scan (5M rows returned)	~0.92 seconds	WHERE score >= 50.0 on 10M rows; buffer pool warm
Cached query — first run	~0.384 seconds	Scan + result build + cache store
Cached query — second	~0.340 seconds	Cache hit — pre-built wire bytes sent directly

Query Type	Result	Details
run		
Cached query speedup	36% faster	Remaining time is kernel TCP send for 2M rows
Memory footprint (10M rows)	~495 MB RSS	Buffer pool + Robin Hood index in RAM
Crash recovery (223 MB WAL)	< 4 seconds	Full WAL replay + index rebuild
Unit tests	21/21 passed	Zero failures

13.4 Optimization Impact Breakdown

Optimization	What It Does	Impact
Batch INSERT (16,384 rows)	Amortizes TCP round-trip + lock overhead	~40x vs. single-row inserts
Robin Hood index	O(1) cache-friendly PK lookup	Point queries at 0.023 ms avg
LRU cache + pre-built wire bytes	Skips re-scan and re-serialization	36% faster on cache hits
Async WAL thread	Decouples fdatasync from INSERT path	Enables 700k–985k rows/sec
Per-table buffer pool (8192 frames)	Hot pages stay in RAM across queries	Low page fault rate on warm workload
TCP_NODELAY + 16 MB socket buffers	Eliminates Nagle delay, reduces send calls	Cuts latency on small responses
CPU warm-up loop (300ms)	Forces CPU into turbo frequency	Consistent first-run benchmark numbers
-O3 -march=native -flto -ffast-math	Full ISA + link-time inlining + fast FP	20–40% over -O2 baseline
pread/pwrite position-independent I/O	Thread-safe disk I/O — no mutex at file layer	Concurrent buffer pool access
Two-level reader-writer locking	Multiple concurrent SELECTs with zero contention	Linear read throughput scaling

13.5 Benchmark Reproducibility

To guarantee reproducible results:

- Compiler: g++ -O3 -march=native -flto -ffast-math
- Clean state: killall -9 flexql_server && rm -rf data/*/* before each run
- CPU warm-up: 300 ms busy-loop inside server startup normalises CPU turbo scaling

- Network: loopback (127.0.0.1) eliminates variable network latency
- Single benchmark process: no other concurrent write workloads

14. Requirement Checklist

14.1 Requirement-to-Implementation Matrix

Requirement	File / Function	Evidence
Multi-threaded server	server_main.cpp / ThreadPool	2×hw_concurrency worker threads, each handles one client connection
Out-of-core (> RAM)	disk_manager.hpp / buffer_pool.hpp	8KB pages + LRU eviction; 100M rows without OOM
CREATE TABLE (all 4 types)	sql_engine.cpp: parse_create_table	INT, DECIMAL, VARCHAR(n), DATETIME, TEXT all validated
INSERT with batch	sql_engine.cpp: parse_insert	Multi-row VALUES syntax, TTL, EXPIRES
SELECT * and columns	sql_engine.cpp: execute_select	All 3 strategies; ORDER BY supported
WHERE single condition	sql_engine.cpp: parse_condition	=, !=, <, <=, >, >= — type-aware comparison
INNER JOIN	sql_engine.cpp: execute_select (join path)	Hash join O(N+M); range join fallback
Primary key indexing	robin_hood_index.hpp	Robin Hood O(1) for INT; unordered_map for VARCHAR
LRU query cache	sql_engine.cpp: QueryCache	512-entry → 2048-entry LRU; version-based invalidation
Cache hit indicator	benchmark output	cached_query_second_seconds shows 36% speedup
Expiration / TTL	table_iterator.hpp: row_alive()	Lazy eval; TTL, EXPIRES unix, EXPIRES datetime
Crash recovery / WAL	wal.hpp + server_main.cpp startup	Async worker + WAL::replay() on restart
Required C API (4 functions)	include/flexql.h + flexql_client.cpp	flexql_open/close/exec/free — exact signatures
Opaque FlexQL handle	flexql_client.cpp	struct FlexQL { int fd; } — hidden from callers
FLEXQL_OK=0, FLEXQL_ERROR=1	include/flexql.h	Plus NOMEM=2, NETWORK_ERROR=3, PROTOCOL_ERROR=4, SQL_ERROR=5

15. Summary

FlexQL is a complete, from-scratch relational database engine that implements all required features: a TCP client-server architecture, a C-compatible client API, SQL parsing and execution, disk-based page storage with a buffer pool, Robin Hood primary key indexing, LRU query caching with version-based invalidation, row-level TTL expiration, a multithreaded server with per-table readers-writer locking, Write-Ahead Log crash recovery, and a hash join for INNER JOIN queries.

Every component was designed with the 10-million-row benchmark in mind. The result is a system that sustains close to one million inserts per second, answers primary key lookups in under 25 microseconds, and scales to 100 million rows without out-of-memory failures.

The full source code is available at: https://github.com/Ludirm02/FlexQL
